

Package ‘rootSolve’

October 5, 2015

Version 1.6.6

Title Nonlinear Root Finding, Equilibrium and Steady-State Analysis of Ordinary Differential Equations

Author Karline Soetaert [aut, cre],
yale sparse matrix package authors [cph]

Maintainer Karline Soetaert <karline.soetaert@nioz.nl>

Depends R (>= 2.01)

Imports stats, graphics, grDevices

Description Routines to find the root of nonlinear functions, and to perform steady-state and equilibrium analysis of ordinary differential equations (ODE). Includes routines that: (1) generate gradient and Jacobian matrices (full and banded), (2) find roots of non-linear equations by the Newton-Raphson method, (3) estimate steady-state conditions of a system of (differential) equations in full, banded or sparse form, using the Newton-Raphson method, or by dynamically running, (4) solve the steady-state conditions for uni-and multicomponent 1-D, 2-D, and 3-D partial differential equations, that have been converted to ODEs by numerical differencing (using the method-of-lines approach). Includes fortran code.

License GPL (>= 2)

rootSolve-package *Roots and steady-states*

Description

Functions that:

- (1) generate gradient and Jacobian matrices (full and banded),
- (2) find roots of non-linear equations by the Newton-Raphson method,
- (3) estimate steady-state conditions of a system of (differential) equations in full, banded or sparse form, using the Newton-Raphson method or by a dynamic run,
- (4) solve the steady-state conditions for uni- and multicomponent 1-D, 2-D and 3-D partial differential equations, that have been converted to ODEs by numerical differencing (using the method-of-lines approach).

Details

Package: rootSolve
 Type: Package
 Version: 1.7
 Date: 2010-10-10
 License: GNU Public License 2 or above

rootSolve was created to solve the examples from chapter 7 (stability and steady-state) from the book of Soetaert and Herman, 2009.

Please cite this work when using rootSolve.

 gradient

Estimates the gradient matrix for a simple function

Description

Given a vector of variables (x), and a function (f) that estimates one function value or a set of function values ($f(x)$), estimates the gradient matrix, containing, on rows i and columns j

$$d(f(x)_i)/d(x_j)$$

The gradient matrix is not necessarily square.

Usage

```
gradient(f, x, centered = FALSE, pert = 1e-8, ...)
```

Arguments

<code>f</code>	function returning one function value, or a vector of function values.
<code>x</code>	either one value or a vector containing the x-value(s) at which the gradient matrix should be estimated.
<code>centered</code>	if TRUE, uses a centered difference approximation, else a forward difference approximation.
<code>pert</code>	numerical perturbation factor; increase depending on precision of model solution.
<code>...</code>	other arguments passed to function <code>f</code> .

Details

the function `f` that estimates the function values will be called as `f(x, ...)`. If `x` is a vector, then the first argument passed to `f` should also be a vector.

The gradient is estimated numerically, by perturbing the x-values.

Value

The gradient matrix where the number of rows equals the length of `f` and the number of columns equals the length of `x`.

the elements on i -th row and j -th column contain: $d((f(x))_i)/d(x_j)$

Note

`gradient` can be used to calculate so-called sensitivity functions, that estimate the effect of parameters on output variables.

```

hessian

Estimates the hessian matrix

Description

Given a vector of variables (x), and a function (f) that estimates one function value, estimates the hessian matrix by numerical differencing. The hessian matrix is a square matrix of second-order partial derivatives of the function f with respect to x . It contains, on rows i and columns j

$$d^2(f(x))/d(x_i)/d(x_j)$$

Usage

```
hessian(f, x, centered = FALSE, pert = 1e-8, ...)
```

Arguments

f	function returning one function value, or a vector of function values.
x	either one value or a vector containing the x-value(s) at which the hessian matrix should be estimated.
centered	if TRUE, uses a centered difference approximation, else a forward difference approximation.
pert	numerical perturbation factor; increase depending on precision of model solution.
...	other arguments passed to function f.

Details

Function `hessian(f, x)` returns a forward or centered difference approximation of the gradient, which itself is also estimated by differencing. Because of that, it is not very precise.

Value

The gradient matrix where the number of rows equals the length of `f` and the number of columns equals the length of `x`.

the elements on *i*-th row and *j*-th column contain: $d((f(x))_i)/d(x_j)$

```

jacobian.band	<i>Banded jacobian matrix for a system of ODEs (ordinary differential equations)</i>
---------------	--

Description

Given a vector of (state) variables y , and a function that estimates a function value for each (state) variable (e.g. the rate of change), estimates the Jacobian matrix $(d(f(y))/d(y))$.

Assumes a banded structure of the Jacobian matrix, i.e. where the non-zero elements are restricted to a number of bands above and below the diagonal.

Usage

```
jacobian.band(y, func, bandup = 1, banddown = 1,
             dy = NULL, time = 0, parms = NULL, pert = 1e-8, ...)
```

Arguments

<code>y</code>	(state) variables, a vector; if <code>y</code> has a name attribute, the names will be used to label the jacobian matrix columns.
<code>func</code>	function that calculates one function value for each element of <code>y</code> ; if an ODE system, <code>func</code> calculates the rate of change (see details).
<code>bandup</code>	number of nonzero bands above the diagonal of the Jacobian matrix.
<code>banddown</code>	number of nonzero bands below the diagonal of the Jacobian matrix.
<code>dy</code>	reference function value; if not specified, it will be estimated by calling <code>func</code> .
<code>time</code>	time, passed to function <code>func</code> .
<code>parms</code>	parameter values, passed to function <code>func</code> .
<code>pert</code>	numerical perturbation factor; increase depending on precision of model solution.
<code>...</code>	other arguments passed to function <code>func</code> .

Details

The function `func` that estimates the rate of change of the state variables has to be consistent with functions called from R-package `deSolve`, which contains integration routines.

This function call is as: **function(time,y,parms,...)** where

- `y`: (state) variable values at which the Jacobian is estimated.
- `parms`: parameter vector - need not be used.
- `time`: time at which the Jacobian is estimated - in general, `time` will not be used.
- `...`: (optional) any other arguments

The Jacobian is estimated numerically, by perturbing the `x`-values.

Value

Jacobian matrix, in banded format, i.e. only the nonzero bands near the diagonal form the rows of the Jacobian.

this matrix has bandup+banddown+1 rows, while the number of columns equal the length of y.

Thus, if the full Jacobian is given by:

	[,1],	[,2],	[,3],	[,4]
[,1]	1	2	0	0
[,2]	3	4	5	0
[,3]	0	6	7	8
[,4]	0	0	9	10

the banded jacobian will be:

	[,1],	[,2],	[,3],	[,4]
[,1]	0	2	5	8
[,2]	1	4	7	10
[,3]	3	6	9	0

```
## =====
mod <- function (t = 0, y, parms = NULL, ...) {
  dy1 <- y[1] + 2*y[2]
  dy2 <- -3*y[1] + 4*y[2] + 5*y[3]
  dy3 <- 6*y[2] + 7*y[3] + 8*y[4]
  dy4 <- 9*y[3] + 10*y[4]
  return(as.list(c(dy1, dy2, dy3, dy4)))
}

jacobian.band(y = c(1, 2, 3, 4), func = mod)
```

jacobian.full	<i>Full square jacobian matrix for a system of ODEs (ordinary differential equations)</i>
---------------	---

Description

Given a vector of (state) variables, and a function that estimates one function value for each (state) variable (e.g. the rate of change), estimates the Jacobian matrix $(d(f(x))/d(x))$

Assumes a full and square Jacobian matrix

Usage

```
jacobian.full(y, func, dy = NULL, time = 0, parms = NULL,
             pert = 1e-8, ...)
```

Arguments

y	(state) variables, a vector; if y has a name attribute, the names will be used to label the Jacobian matrix columns.
func	function that calculates one function value for each element of y; if an ODE system, func calculates the rate of change (see details).
dy	reference function value; if not specified, it will be estimated by calling func.
time	time, passed to function func.
parms	parameter values, passed to function func.
pert	numerical perturbation factor; increase depending on precision of model solution.
...	other arguments passed to function func.

Details

The function func that estimates the rate of change of the state variables has to be consistent with functions called from R-package deSolve, which contains integration routines.

This function call is as: **function(time,y,parms,...)** where

- y : (state) variable values at which the Jacobian is estimated.
- parms: parameter vector - need not be used.
- time: time at which the Jacobian is estimated - in general, time will not be used.
- ...: (optional) any other arguments.

The Jacobian is estimated numerically, by perturbing the x-values.

Value

The square jacobian matrix; the elements on i-th row and j-th column are given by: $d(f(x)_i)/d(x_j)$

Note

This function is useful for stability analysis of ODEs, which start by estimating the Jacobian at equilibrium points. The type of equilibrium then depends on the eigenvalue of the Jacobian.

```

multiroot	<i>Solves for n roots of n (nonlinear) equations.</i>
-----------	---

Description

Given a vector of n variables, and a set of n (nonlinear) equations in these variables, estimates the root of the equations, i.e. the variable values where all function values = 0.

Assumes a full Jacobian matrix, uses the Newton-Raphson method.

Usage

```
multiroot(f, start, maxiter = 100,
          rtol = 1e-6, atol = 1e-8, ctol = 1e-8,
          useFortran = TRUE, positive = FALSE,
          jacfunc = NULL, jactype = "fullint",
          verbose = FALSE, bandup = 1, banddown = 1,
          parms = NULL, ...)
```

Arguments

f	function for which the root is sought; it must return a vector with as many values as the length of start. It is called either as $f(x, \dots)$ if <code>parms = NULL</code> or as $f(x, parms, \dots)$ if <code>parms</code> is not <code>NULL</code> .
start	vector containing initial guesses for the unknown x ; if <code>start</code> has a name attribute, the names will be used to label the output vector.
maxiter	maximal number of iterations allowed.
rtol	relative error tolerance, either a scalar or a vector, one value for each element in the unknown x .
atol	absolute error tolerance, either a scalar or a vector, one value for each element in x .
ctol	a scalar. If between two iterations, the maximal change in the variable values is less than this amount, then it is assumed that the root is found.
useFortran	logical, if <code>FALSE</code> , then an R -implementation of the Newton-Raphson method is used - see details.
positive	if <code>TRUE</code> , the unknowns y are forced to be non-negative numbers.

jacfunc	<p>if not NULL, a user-supplied R function that estimates the Jacobian of the system of differential equations $dy(i)/dy(j)$. In some circumstances, supplying jacfunc can speed up the computations. The R calling sequence for jacfunc is identical to that of f.</p> <p>If the Jacobian is a full matrix, jacfunc should return a matrix $dydot/dy$, where the ith row contains the derivative of dy_i/dt with respect to y_j, or a vector containing the matrix elements by columns.</p> <p>If the Jacobian is banded, jacfunc should return a matrix containing only the nonzero bands of the jacobian, ($dydot/dy$), rotated row-wise.</p>
jactype	<p>the structure of the Jacobian, one of "fullint", "fullusr", "bandusr", "bandint", or "sparse" - either full or banded and estimated internally or by the user, or arbitrary sparse. If the latter, then the solver will call, <code>stodes</code>, else <code>stode</code></p> <p>If the Jacobian is arbitrarily "sparse", then it will be calculated by the solver (i.e. it is not possible to also specify jacfunc).</p>
verbose	if TRUE: full output to the screen, e.g. will output the steady-state settings.
bandup	number of non-zero bands above the diagonal, in case the Jacobian is banded.
banddown	number of non-zero bands below the diagonal, in case the jacobian is banded.
parms	vector or list of parameters used in f or jacfunc.
...	additional arguments passed to function f.

Details

`start` gives the initial guess for each variable; different initial guesses may return different roots.

The input parameters `rtol`, and `atol` determine the **error control** performed by the solver.

The solver will control the vector **e** of estimated local errors in **f**, according to an inequality of the form $\max\text{-norm of } (\mathbf{e}/\mathbf{ewt}) \leq 1$, where **ewt** is a vector of positive error weights. The values of `rtol` and `atol` should all be non-negative.

The form of **ewt** is:

$$\mathbf{rtol} \times \mathbf{abs}(\mathbf{f}) + \mathbf{atol}$$

where multiplication of two vectors is element-by-element.

In addition, the solver will stop if between two iterations, the maximal change in the values of **x** is less than `ctol`.

There is no checking whether the requested precision exceeds the capabilities of the machine.

Value

a list containing:

<code>root</code>	the location (x-values) of the root.
<code>f.root</code>	the value of the function evaluated at the root.
<code>iter</code>	the number of iterations used.
<code>estim.precis</code>	the estimated precision for root. It is defined as the mean of the absolute function values ($\text{mean}(\mathbf{abs}(\mathbf{f}.\mathbf{root}))$).

Note

The Fortran implementation of the Newton-Raphson method function (the default) is generally faster than the R implementation. The R implementation has been included for didactic purposes.

`multiroot` makes use of function `stode`. Technically, it is just a wrapper around function `stode`. If the sparsity structure of the Jacobian is known, it may be more efficiently to call `stode`, `stodes`, `steady`, `steady.1D`, `steady.2D`, `steady.3D`. It is NOT guaranteed that the method will converge to the root.

## example 3: find a matrix
## =====

f2<-function(x) {
  X <- matrix(nrow = 5, x)
  X %*% X %*% X -matrix(nrow = 5, data = 1:25, byrow = TRUE)
}
x <- multiroot(f2, start = 1:25 )$root
X <- matrix(nrow = 5, x)

X%*%X%*%X

```

multiroot.1D

Solves for n roots of n (nonlinear) equations, created by discretizing ordinary differential equations.

Description

multiroot.1D finds the solution to boundary value problems of ordinary differential equations, which are approximated using the method-of-lines approach.

Assumes a banded Jacobian matrix, uses the Newton-Raphson method.

Usage

```

multiroot.1D(f, start, maxiter = 100,
             rtol = 1e-6, atol = 1e-8, ctol = 1e-8,
             nspec = NULL, dimens = NULL, verbose = FALSE,
             positive = FALSE, names = NULL, parms = NULL, ...)

```

Arguments

f	function for which the root is sought; it must return a vector with as many values as the length of start. It is called either as $f(x, \dots)$ if <code>parms = NULL</code> or as $f(x, parms, \dots)$ if <code>parms</code> is not <code>NULL</code> .
start	vector containing initial guesses for the unknown x ; if <code>start</code> has a name attribute, the names will be used to label the output vector.
maxiter	maximal number of iterations allowed.
rtol	relative error tolerance, either a scalar or a vector, one value for each element in the unknown x .
atol	absolute error tolerance, either a scalar or a vector, one value for each element in x .
ctol	a scalar. If between two iterations, the maximal change in the variable values is less than this amount, then it is assumed that the root is found.
nspec	the number of <i>*species*</i> (components) in the model. If <code>NULL</code> , then <code>dimens</code> should be specified.
dimens	the number of <i>*boxes*</i> in the model. If <code>NULL</code> , then <code>nspec</code> should be specified.
verbose	if <code>TRUE</code> : full output to the screen, e.g. will output the steady-state settings.
positive	if <code>TRUE</code> , the unknowns y are forced to be non-negative numbers.
names	the names of the components; used to label the output, which will be written as a matrix.
parms	vector or list of parameters used in f .
...	additional arguments passed to function f .

Details

`multiroot.1D` is similar to `steady.1D`, except for the function specification which is simpler in `multiroot.1D`.

It is to be used to solve (simple) boundary value problems of differential equations.

The following differential equation:

$$0 = f(x, y, \frac{dy}{dx}, \frac{d^2y}{dx^2})$$

with boundary conditions

$y_{x=a} = ya$, at the start and $y_{x=b}=yb$ at the end of the integration interval $[a,b]$ is approximated as follows:

1. First the integration interval x is discretized, for instance:

```
dx <- 0.01
```

```
x <- seq(a,b,by=dx)
```

where dx should be small enough to keep numerical errors small.

2. Then the first- and second-order derivatives are differenced on this numerical grid. R's `diff` function is very efficient in taking numerical differences, so it is used to approximate the first-, and second-order derivatives as follows.

A *first-order derivative* y' can be approximated either as:

$y' = \text{diff}(c(y_a, y)) / dx$ if only the initial condition y_a is prescribed,

$y' = \text{diff}(c(y, y_b)) / dx$ if only the final condition, y_b is prescribed,

$y' = 0.5 * (\text{diff}(c(y_a, y)) / dx + \text{diff}(c(y, y_b)) / dx)$ if initial, y_a , and final condition, y_b are prescribed.

The latter (centered differences) is to be preferred.

A *second-order derivative* y'' can be approximated by differencing twice.

$y'' = \text{diff}(\text{diff}(c(y_a, y, y_b)) / dx) / dx$

3. Finally, function `multiroot.1D` is used to locate the root.

See the examples

Value

a list containing:

<code>root</code>	the values of the root.
<code>f.root</code>	the value of the function evaluated at the root.
<code>iter</code>	the number of iterations used.
<code>estim.precis</code>	the estimated precision for root. It is defined as the mean of the absolute function values (<code>mean(abs(f.root))</code>).

Note

`multiroot.1D` makes use of function `steady.1D`.

It is NOT guaranteed that the method will converge to the root.

plot.steady1D	<i>Plot and Summary Method for steady1D, steady2D and steady3D Objects</i>
---------------	--

Description

Plot the output of steady-state solver routines.

Usage

```

## S3 method for class 'steady1D'
plot(x, ..., which = NULL, grid = NULL,
     xyswap = FALSE, ask = NULL,
     obs = NULL, obspar = list(), vertical = FALSE)
## S3 method for class 'steady2D'
image(x, which = NULL, add.contour = FALSE,
      grid = NULL, ask = NULL,
      method = "image", legend = FALSE, ...)
## S3 method for class 'steady2D'
subset(x, which = NULL, ...)
## S3 method for class 'steady3D'
image(x, which = NULL, dimselect = NULL,
      add.contour = FALSE, grid = NULL, ask = NULL,
      method = "image", legend = FALSE, ...)
## S3 method for class 'rootSolve'
summary(object, ...)

```

Arguments

x an object of class steady1D, or steady2D as returned by the solvers steady.1D and steady.2D, and to be plotted.
For steady1D objects, it is allowed to pass several objects after x (unnamed) - see second example.

which	the name(s) or the index to the variables that should be plotted. Default = all variables.
grid	For 1-D plots of output generated with <code>steady.1D</code> , a vector of values against which the 1-D steady-state solution has to be plotted. If NULL, then steady-state solutions are plotted against the index. for image plots of output generated with <code>steady.2D</code> or <code>steady.3D</code> : the x- and y-grid, as a list.
ask	logical; if TRUE, the user is <i>asked</i> before each plot, if NULL the user is only asked if more than one page of plots is necessary and the current graphics device is set interactive, see <code>par(ask=.)</code> and <code>dev.interactive</code> .
xyswap	if TRUE, then x-and y-values are swapped and the y-axis is from top to bottom. Useful for drawing vertical profiles.
vertical	if TRUE, then 1. x-and y-values are swapped, the y-axis is from top to bottom, the x-axis is on top, margin 3 and the main title gets the value of the x-axis. Useful for drawing vertical profiles; see example 2.
obs	a data.frame or matrix with "observed data" that will be added as points to the plots. obs can also be a list with multiple data.frames and/or matrices containing observed data. The first column of obs should contain the grid-variables as specified in argument grid. The other columns contain the observed values and they should have names that are known in x. If the first column of obs consists of factors, or characters (strings), then it is assumed that the data are presented in long (database) format, where the first three columns contain (name, grid, value). If obs is not NULL and which is NULL, then the variables, common to both obs and x will be plotted.
obspar	additional graphics arguments passed to points, for plotting the observed data. If obs is a list containing multiple observed data sets, then the graphics arguments can be a vector or a list (e.g. for xlim, ylim), specifying each data set separately.
dimselect	a list or NULL. The dimension over which the 3-D image loops. If NULL, will loop over the 3rd (z) dimension. This is similar as setting <code>dimselect = list(z = 1:Nz)</code> where Nz is the number of grid cells in the 3rd dimension; setting <code>dimselect = list(z = seq(1, Nz, by = 2))</code> will loop over the 3rd dimension, but every 2nd cell; <code>dimselect = list(x = ...)</code> or <code>dimselect = list(y = ...)</code> will loop over the x respectively y-dimension. See <code>steady.3D</code> for some examples.
add.contour	if TRUE, will add contours to the image plot.
method	the name of the plotting function to use, one of "image", "filled.contour", "contour" or "persp".
legend	if TRUE, a color legend will be drawn next to the "image", or "persp" plot.
object	object of class <code>rootSolve</code> whose summary has to be calculated.
...	additional arguments passed to the methods. The graphical arguments are passed to <code>plot.default</code> (for 1D) or <code>image</code> (for 2D, 3D)

For `plot.steady1D`, the dots may contain other objects of class `steady1D`, as returned by `steady.1D`, and to be plotted on the same graphs as `x` - see second example. `x` and these other objects should be compatible, i.e. the column names should be the same.

For `plot.steady1D`, the arguments after ... must be matched exactly.

Details

The number of panels per page is automatically determined up to 3 x 3 (`par(mfrow=c(3, 3))`). This default can be overwritten by specifying user-defined settings for `mfrow` or `mfcoll`. Set `mfrow` equal to `NULL` to avoid the plotting function to change user-defined `mfrow` or `mfcoll` settings

Other graphical parameters can be passed as well. Parameters are vectorized, either according to the number of plots (`xlab`, `ylab`, `main`, `sub`, `xlim`, `ylim`, `log`, `asp`, `ann`, `axes`, `frame.plot`, `panel.first`, `panel.last`, `cex.lab`, `cex.axis`, `cex.main`) or according to the number of lines within one plot (other parameters e.g. `col`, `lty`, `lwd` etc.) so it is possible to assign specific axis labels to individual plots, resp. different plotting style. Plotting parameter `ylim`, or `xlim` can also be a list to assign different axis limits to individual plots.

Similarly, the graphical parameters for observed data, as passed by `obspar` can be vectorized, according to the number of observed data sets.

For `steady3D` objects, 2-D images are generated by looping over one of the axes; by default the third axis. See [steady.3D](#).

```

runsteady	<i>Dynamically runs a system of ordinary differential equations (ODE) to steady-state</i>
-----------	---

Description

Solves the steady-state condition of ordinary differential equations (ODE) in the form:

$$dy/dt = f(t, y)$$

by dynamically running till the summed absolute values of the derivatives become smaller than some predefined tolerance.

The R function runsteady makes use of the FORTRAN ODE solver DLSODE, written by Alan C. Hindmarsh and Andrew H. Sherman

The system of ODE's is written as an R function or defined in compiled code that has been dynamically loaded. The user has to specify whether or not the problem is stiff and choose the appropriate solution method (e.g. make choices about the type of the Jacobian).

Usage

```

runsteady(y, times = c(0, Inf), func, parms,
         stol = 1e-8, rtol = 1e-6, atol = 1e-6,
         jacfunc = NULL, jactype = "fullint", mf = NULL,
         verbose = FALSE, tcrit = NULL, hmin = 0, hmax = NULL,
         hini = 0, ynames = TRUE, maxord = NULL, bandup = NULL,
         banddown = NULL, maxsteps = 100000, dllname = NULL,
         initfunc = dllname, initpar = parms, rpar = NULL,
         ipar = NULL, nout = 0, outnames = NULL,
         forcings = NULL, initforc = NULL, fcontrol = NULL, ...)

```

Arguments

y	the initial (state) values for the ODE system. If y has a name attribute, the names will be used to label the output matrix.
times	The simulation time. This should be a 2-valued vector, consisting of the initial time and the end time. The last time value should be large enough to make sure that steady-state is effectively reached in this period. The simulation will stop either when times[2] has been reached or when maxsteps have been performed.
func	<p>either an R-function that computes the values of the derivatives in the ODE system (the <i>model definition</i>) at time t, or a character string giving the name of a compiled function in a dynamically loaded shared library.</p> <p>If func is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code>. t is the current time point in the integration, y is the current estimate of the variables in the ODE system. If the initial values y has a names attribute, the names will be available inside func. parms is a vector or list of parameters; ... (optional) are any other arguments passed to the function.</p> <p>The return value of func should be a list, whose first element is a vector containing the derivatives of y with respect to time, and whose next elements are global values that are required at each point in times.</p> <p>The derivatives should be specified in the same order as the state variables y.</p>
parms	vector or list of parameters used in func or jacfunc.
stol	steady-state tolerance; it is assumed that steady-state is reached if the average of absolute values of the derivatives drops below this number.
rtol	relative error tolerance of integrator, either a scalar or an array as long as y. See details.
atol	absolute error tolerance of integrator, either a scalar or an array as long as y. See details.
jacfunc	<p>if not NULL, an R function that computes the jacobian of the system of differential equations $dy(i)/dy(j)$, or a string giving the name of a function or subroutine in 'dllname' that computes the jacobian (see Details below for more about this option). In some circumstances, supplying jacfunc can speed up the computations, if the system is stiff. The R calling sequence for jacfunc is identical to that of func.</p> <p>If the jacobian is a full matrix, jacfunc should return a matrix $dydot/dy$, where the ith row contains the derivative of dy_i/dt with respect to y_j, or a vector containing the matrix elements by columns (the way R and Fortran store matrices). If the jacobian is banded, jacfunc should return a matrix containing only the nonzero bands of the jacobian, rotated row-wise. See first example of lsode.</p>
jactype	the structure of the jacobian, one of "fullint", "fullusr", "bandusr" or "bandint" - either full or banded and estimated internally or by user; overruled if mf is not NULL.
mf	the "method flag" passed to function lsode - overrules jactype - provides more options than jactype - see details.
verbose	if TRUE: full output to the screen, e.g. will output the settings of vectors *istate* and *rstate* - see details.

tcrit	if not NULL, then lsode cannot integrate past tcrit. The Fortran routine lsode overshoots its targets (times points in the vector times), and interpolates values for the desired time points. If there is a time beyond which integration should not proceed (perhaps because of a singularity), that should be provided in tcrit.
hmin	an optional minimum value of the integration stepsize. In special situations this parameter may speed up computations with the cost of precision. Don't use hmin if you don't know why!
hmax	an optional maximum value of the integration stepsize. If not specified, hmax is set to the largest difference in times, to avoid that the simulation possibly ignores short-term events. If 0, no maximal size is specified.
hini	initial step size to be attempted; if 0, the initial step size is determined by the solver.
ynames	if FALSE: names of state variables are not passed to function func ; this may speed up the simulation.
maxord	the maximum order to be allowed. NULL uses the default, i.e. order 12 if implicit Adams method (meth=1), order 5 if BDF method (meth=2). Reduce maxord to save storage space.
bandup	number of non-zero bands above the diagonal, in case the jacobian is banded.
banddown	number of non-zero bands below the diagonal, in case the jacobian is banded.
maxsteps	maximal number of steps. The simulation will stop either when maxsteps have been performed or when times[2] has been reached.
dllname	a string giving the name of the shared library (without extension) that contains all the compiled function or subroutine definitions referred to in func and jacfunc. See package vignette.
initfunc	if not NULL, the name of the initialisation function (which initialises values of parameters), as provided in 'dllname'. See package vignette.
initpar	only when 'dllname' is specified and an initialisation function initfunc is in the dll: the parameters passed to the initialiser, to initialise the common blocks (fortran) or global variables (C, C++).
rpar	only when 'dllname' is specified: a vector with double precision values passed to the dll-functions whose names are specified by func and jacfunc.
ipar	only when 'dllname' is specified: a vector with integer values passed to the dll-functions whose names are specified by func and jacfunc.
nout	only used if dllname is specified and the model is defined in compiled code: the number of output variables calculated in the compiled function func, present in the shared library. Note: it is not automatically checked whether this is indeed the number of output variables calculated in the dll - you have to perform this check in the code - See package vignette of deSolve.
outnames	only used if 'dllname' is specified and nout > 0: the names of output variables calculated in the compiled function func, present in the shared library.
forcings	only used if 'dllname' is specified: a vector with the forcing function values, or a list with the forcing function data sets, each present as a two-columned matrix, with (time,value); interpolation outside the interval [min(times), max(times)] is done by taking the value at the closest data extreme.

	This feature is here for compatibility with models defined in compiled code from package deSolve; see deSolve's package vignette "compiledCode".
initforc	if not NULL, the name of the forcing function initialisation function, as provided in 'dllname'. It MUST be present if forcings has been given a value. See deSolve's package vignette "compiledCode".
fcontrol	A list of control parameters for the forcing functions. See deSolve's package vignette "compiledCode".
...	additional arguments passed to func and jacfunc allowing this to be a generic function.

Details

The work is done by the Fortran subroutine `dlode`, whose documentation should be consulted for details (it is included as comments in the source file 'src/lode.f'). The implementation is based on the November, 2003 version of `lsode`, from Netlib.

Before using `runsteady`, the user has to decide whether or not the problem is stiff.

If the problem is nonstiff, use method flag `mf = 10`, which selects a nonstiff (Adams) method, no Jacobian used..

If the problem is stiff, there are four standard choices which can be specified with `jactype` or `mf`.

The options for **jactype** are

- `jactype = "fullint"` : a full jacobian, calculated internally by `lsode`, corresponds to `mf=22`.
- `jactype = "fullusr"` : a full jacobian, specified by user function `jacfunc`, corresponds to `mf=21`.
- `jactype = "bandusr"` : a banded jacobian, specified by user function `jacfunc`; the size of the bands specified by `bandup` and `banddown`, corresponds to `mf=24`.
- `jactype = "bandint"` : a banded jacobian, calculated by `lsode`; the size of the bands specified by `bandup` and `banddown`, corresponds to `mf=25`.

More options are available when specifying **mf** directly.

The legal values of `mf` are 10, 11, 12, 13, 14, 15, 20, 21, 22, 23, 24, 25.

`mf` is a positive two-digit integer, $mf = (10 * METH + MITER)$, where

- `METH` indicates the basic linear multistep method: `METH = 1` means the implicit Adams method. `METH = 2` means the method based on backward differentiation formulas (BDF-s).
- `MITER` indicates the corrector iteration method: `MITER = 0` means functional iteration (no Jacobian matrix is involved). `MITER = 1` means chord iteration with a user-supplied full (NEQ by NEQ) Jacobian. `MITER = 2` means chord iteration with an internally generated (difference quotient) full Jacobian (using NEQ extra calls to `func` per `df/dy` value). `MITER = 3` means chord iteration with an internally generated diagonal Jacobian approximation (using 1 extra call to `func` per `df/dy` evaluation). `MITER = 4` means chord iteration with a user-supplied banded Jacobian. `MITER = 5` means chord iteration with an internally generated banded Jacobian (using `ML+MU+1` extra calls to `func` per `df/dy` evaluation).

If `MITER = 1` or 4, the user must supply a subroutine `jacfunc`.

Inspection of the example below shows how to specify both a banded and full jacobian.

The input parameters `rtol`, and `atol` determine the **error control** performed by the solver.

See [stode](#) for details.

Models may be defined in compiled C or Fortran code, as well as in an R-function. See function [stode](#) for details.

The output will have the **attributes** `*istate*`, and `*rstate*`, two vectors with several useful elements.

if `verbose = TRUE`, the settings of `istate` and `rstate` will be written to the screen.

the following elements of **istate** are meaningful:

- `el 1` : gives the conditions under which the last call to the integrator returned. 2 if `lsode` was successful, -1 if excess work done, -2 means excess accuracy requested. (Tolerances too small), -3 means illegal input detected. (See printed message.), -4 means repeated error test failures. (Check all input), -5 means repeated convergence failures. (Perhaps bad Jacobian supplied or wrong choice of MF or tolerances.), -6 means error weight became zero during problem. (Solution component `i` vanished, and `atol` or `atol(i) = 0.`)
- `el 12` : The number of steps taken for the problem so far.
- `el 13` : The number of evaluations for the problem so far.,
- `el 14` : The number of Jacobian evaluations and LU decompositions so far.,
- `el 15` : The method order last used (successfully),.
- `el 16` : The order to be attempted on the next step.,
- `el 17` : if `el 1 = -4, -5`: the largest component in the error vector,

rstate contains the following:

- 1: The step size in `t` last used (successfully).
- 2: The step size to be attempted on the next step.
- 3: The current value of the independent variable which the solver has actually reached, i.e. the current internal mesh point in `t`.
- 4: A tolerance scale factor, greater than 1.0, computed when a request for too much accuracy was detected.

For more information, see the comments in the original code `lsode.f`

Value

A list containing

- `y` a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. If `y` has a `names` attribute, it will be used to label the output values.
- `...` the number of "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached, the attribute `precis` with the precision attained at the last iteration estimated as the mean absolute rate of change ($\text{sum}(\text{abs}(\text{dy}))/n$), the attribute `time` with the simulation time reached and the attribute `steps` with the number of steps performed.

The output will also have the attributes `istate`, and `rstate`, two vectors with several useful elements of the dynamic simulation. See details. The first element of `istate` returns the conditions under which the last call to the integrator returned. Normal is `istate[1] = 2`. If `verbose = TRUE`, the settings of `istate` and `rstate` will be written to the screen.

rbind("Newton Raphson" = ST$y, "Runsteady" = ST2$y)

```

steady

General steady-state solver for a set of ordinary differential equations.

Description

Estimates the steady-state condition for a system of ordinary differential equations.

This is a wrapper around steady-state solvers `stode`, `stodes` and `runsteady`.

Usage

```
steady(y, time = NULL, func, parms = NULL, method = "stode", ...)
```

Arguments

<code>y</code>	the initial guess of (state) values for the ODE system, a vector. If <code>y</code> has a name attribute, the names will be used to label the output matrix.
<code>time</code>	time for which steady-state is wanted; the default is <code>time=0</code> (for method = "stode" or method = "stodes", and <code>time = c(0,Inf)</code> for method = "runsteady".
<code>func</code>	either an R-function that computes the values of the derivatives in the ode system (the model definition) at time <code>time</code> , or a character string giving the name of a compiled function in a dynamically loaded shared library. If <code>func</code> is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code> . <code>t</code> is the current time point in the integration, <code>y</code> is the current estimate of the variables in the ODE system. If the initial values <code>y</code> has a names attribute, the names will be available inside <code>func</code> . <code>parms</code> is a vector or list of parameters; ... (optional) are any other arguments passed to the function. The return value of <code>func</code> should be a list, whose first element is a vector containing the derivatives of <code>y</code> with respect to <code>time</code> , and whose next elements are global values whose steady-state value is also required. The derivatives should be specified in the same order as the state variables <code>y</code> .

parms	parameters passed to func.
method	the solution method to use, one of stode, stodes or runsteady.
...	additional arguments passed to function stode, stodes or runsteady.

Details

This is simply a wrapper around the various steady-state solvers.

See package vignette for information about specifying the model in compiled code.

See the selected solver for the additional options.

Value

A list containing

y	a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. If y has a names attribute, it will be used to label the output values.
...	the number of "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached and the attribute `precis` with the precision attained during each iteration.

Examples

```
## =====
## Bacteria (Bac) growing on a substrate (Sub)
## =====

model <- function(t, state, pars) {
  with(as.list(c(state,pars)), {
    #      substrate uptake          death  respiration
    dBact = gmax*eff*Sub/(Sub+ks)*Bact - dB*Bact - rB*Bact
    dSub  =-gmax  *Sub/(Sub+ks)*Bact + dB*Bact          +input

    return(list(c(dBact, dSub)))
  })
}
```

```

    })
}

pars <- list(gmax = 0.5, eff = 0.5,
            ks = 0.5, rB = 0.01, dB = 0.01, input = 0.1)
# Newton-Raphson
steady(y = c(Bact = 0.1, Sub = 0), time = 0,
      func = model, parms = pars, pos = TRUE)

# Dynamic run to steady-state
as.data.frame(steady(y = c(Bact = 0.1, Sub = 0), time = c(0, 1e5),
                    func = model, parms = pars, method = "runsteady"))

```

steady.1D	<i>Steady-state solver for multicomponent 1-D ordinary differential equations</i>
-----------	---

Description

Estimates the steady-state condition for a system of ordinary differential equations that result from 1-Dimensional partial differential equation models that have been converted to ODEs by numerical differencing.

It is assumed that exchange occurs only between adjacent layers.

Usage

```

steady.1D(y, time = NULL, func, parms = NULL,
         nspec = NULL, dimens = NULL,
         names = NULL, method = "stode",
         cyclicBnd = NULL, bandwidth = 1, ...)

```

Arguments

y	the initial guess of (state) values for the ODE system, a vector.
time	time for which steady-state is wanted; the default is time=0 (for method = "stode" or method = "stodes", and time = c(0, Inf) for method = "runsteady").
func	either an R-function that computes the values of the derivatives in the ode system (the model definition) at time time, or a character string giving the name of a compiled function in a dynamically loaded shared library. If func is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code> . t is the current time point in the integration, y is the current estimate of the variables in the ODE system. If the initial values y has a names attribute, the names will be available inside func. parms is a vector or list of parameters; ... (optional) are any other arguments passed to the function. The return value of func should be a list, whose first element is a vector containing the derivatives of y with respect to time, and whose next elements are global values whose steady-state value is also required.

	The derivatives should be specified in the same order as the state variables y .
parms	parameters passed to func.
nspec	the number of <i>*species*</i> (components) in the model. If NULL, then <i>dimens</i> should be specified.
dimens	the number of <i>*boxes*</i> in the model. If NULL, then <i>nspec</i> should be specified.
names	the names of the components; used to label the output, which will be written as a matrix.
method	the solution method, one of "stode", "stodes" or "runsteady".
cyclicBnd	if a cyclic boundary exists, a value of 1 else NULL; see details.
bandwidth	the number of adjacent boxes over which transport occurs. Normally equal to 1 (box i only interacts with box $i-1$, and $i+1$). Values larger than 1 will not work with <i>method</i> = "stodes".
...	additional arguments passed to the solver function as defined by <i>method</i> .

Details

This is the method of choice for multi-species 1-dimensional models, that are only subjected to transport between adjacent layers

More specifically, this method is to be used if the state variables are arranged per species:

$A[1], A[2], A[3], \dots, B[1], B[2], B[3], \dots$ (for species A, B)

Two methods are implemented.

- The default method rearranges the state variables as $A[1], B[1], \dots, A[2], B[2], \dots, A[3], B[3], \dots$. This reformulation leads to a banded Jacobian with (upper and lower) half bandwidth = number of species. Then function *stode* solves the banded problem.
- The second method uses function *stodes*. Based on the dimension of the problem, the method first calculates the sparsity pattern of the Jacobian, under the assumption that transport is only occurring between adjacent layers. Then *stodes* is called to solve the problem.

As *stodes* is used to estimate steady-state, it may be necessary to specify the length of the real work array, *lrw*.

Although a reasonable guess of *lrw* is made, it is possible that this will be too low. In this case, *steady.1D* will return with an error message telling the size of the work array actually needed. In the second try then, set *lrw* equal to this number.

For single-species 1-D models, use [steady.band](#).

If state variables are arranged as (e.g. $A[1], B[1], A[2], B[2], A[3], B[3], \dots$) then the model should be solved with [steady.band](#)

In some cases, a cyclic boundary condition exists. This is when the first box interacts with the last box and vice versa. In this case, there will be extra non-zero fringes in the Jacobian which need to be taken into account. The occurrence of cyclic boundaries can be toggled on by specifying argument *cyclicBnd*=1. If this is the case, then the steady-state will be estimated using *stodes*. The default is no cyclic boundaries.

Value

A list containing

`y` if `names` is not given: a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. if `names` is given, a matrix with one column for every steady-state **component**.
 ... the number of "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached and the attribute `precis` with the precision attained during each iteration.

Note

It is advisable though not mandatory to specify BOTH `nspec` and `dimens`. In this case, the solver can check whether the input makes sense (i.e. if `nspec*dimens = length(y)`)

steady.2D

Steady-state solver for 2-Dimensional ordinary differential equations

Description

Estimates the steady-state condition for a system of ordinary differential equations that result from 2-Dimensional partial differential equation models that have been converted to ODEs by numerical differencing.

It is assumed that exchange occurs only between adjacent layers.

Usage

```

steady.2D(y, time = 0, func, parms = NULL,
          nspec = NULL, dims,
          names = NULL, cyclicBnd = NULL, ...)

```

Arguments

y the initial guess of (state) values for the ODE system, a vector.

time time for which steady-state is wanted; the default is time=0.

func	<p>either an R-function that computes the values of the derivatives in the ode system (the model definition) at time <code>time</code>, or a character string giving the name of a compiled function in a dynamically loaded shared library. If <code>func</code> is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code>. <code>t</code> is the current time point in the integration, <code>y</code> is the current estimate of the variables in the ODE system. If the initial values <code>y</code> has a <code>names</code> attribute, the names will be available inside <code>func</code>. <code>parms</code> is a vector or list of parameters; ... (optional) are any other arguments passed to the function.</p> <p>The return value of <code>func</code> should be a list, whose first element is a vector containing the derivatives of <code>y</code> with respect to <code>time</code>, and whose next elements are global values whose steady-state value is also required.</p> <p>The derivatives should be specified in the same order as the state variables <code>y</code>.</p>
parms	parameters passed to <code>func</code> .
nspec	the number of <i>*species*</i> (components) in the model.
dimens	a 2-valued vector with the dimensionality of the model, i.e. the number of <i>*boxes*</i> in x- and y-direction.
cyclicBnd	if not NULL then a number or a 2-valued vector with the dimensions where a cyclic boundary is used - 1: x-dimension, 2: y-dimension; see details.
names	the names of the components; used to label the output, and for plotting.
...	additional arguments passed to function <code>stodes</code> . See note.

Details

This is the method of choice for 2-dimensional models, that are only subjected to transport between adjacent layers.

Based on the dimension of the problem, the method first calculates the sparsity pattern of the Jacobian, under the assumption that transport is only occurring between adjacent layers. Then `stodes` is called to find the steady-state.

In some cases, a cyclic boundary condition exists. This is when the first boxes in x-or y-direction interact with the last boxes. In this case, there will be extra non-zero fringes in the Jacobian which need to be taken into account. The occurrence of cyclic boundaries can be toggled on by specifying argument `cyclicBnd`. For instance, `cyclicBnd = 1` indicates that a cyclic boundary is required only for the x-direction, whereas `cyclicBnd = c(1,2)` imposes a cyclic boundary for both x- and y-direction. The default is no cyclic boundaries.

As `stodes` is used, it will probably be necessary to specify the length of the real work array, `lrw`.

Although a reasonable guess of `lrw` is made, it may occur that this will be too low. In this case, `steady.2D` will return with an error message telling that there was insufficient storage. In the second try then, increase `lrw`. you may need to experiment to find suitable value. The smaller the better.

An error message that says to increase `lrw` may look like this:

```
In stodes(y = y, time = time, func = func, parms = parms, nnz = c(nspec,
insufficient storage in nnfc
```

See `stodes` for the additional options.

Value

A list containing

`y` a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations.
 ... the "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached and the attribute `precis` with the precision attained during each iteration. Another attribute, called `dims` returns a.o. the length of the work array actually required. This can be specified with input argument `lrw`. See note and first example

Note

It is advisable though not mandatory to specify BOTH `nspec` and `dimens`. In this case, the solver can check whether the input makes sense (as `nspec*dimens[1]*dimens[2] = length(y)`)
 do NOT use this method for problems that are not 2D.

It is likely that the estimated length of the work array (argument `lrw`), required for the solver `stodes` will be too small. If that is the case, the solver will return with an error saying to increase `lrw`. The current value of the work array can be found via the attributes of the output. See first example.

steady.3D

Steady-state solver for 3-Dimensional ordinary differential equations

Description

Estimates the steady-state condition for a system of ordinary differential equations that result from 3-Dimensional partial differential equation models that have been converted to ODEs by numerical differencing.

It is assumed that exchange occurs only between adjacent layers.

Usage

```

steady.3D(y, time = 0, func, parms = NULL,
  nspec = NULL, dims,
  names = NULL, cyclicBnd = NULL, ...)

```

Arguments

<code>y</code>	the initial guess of (state) values for the ODE system, a vector.
<code>time</code>	time for which steady-state is wanted; the default is <code>time=0</code> .
<code>func</code>	either an R-function that computes the values of the derivatives in the ode system (the model definition) at time <code>time</code> , or a character string giving the name of a compiled function in a dynamically loaded shared library. If <code>func</code> is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code> . <code>t</code> is the current time point in the integration, <code>y</code> is the current estimate of the variables in the ODE system. If the initial values <code>y</code> has a <code>names</code> attribute, the <code>names</code> will be available inside <code>func</code> . <code>parms</code> is a vector or list of parameters; ... (optional) are any other arguments passed to the function. The return value of <code>func</code> should be a list, whose first element is a vector containing the derivatives of <code>y</code> with respect to <code>time</code> , and whose next elements are global values whose steady-state value is also required. The derivatives should be specified in the same order as the state variables <code>y</code> .
<code>parms</code>	parameters passed to <code>func</code> .
<code>nspec</code>	the number of <code>*species*</code> (components) in the model.
<code>dimens</code>	a 3-valued vector with the dimensionality of the model, i.e. the number of <code>*boxes*</code> in x-, y- and z- direction.
<code>cyclicBnd</code>	if not NULL then a number or a 3-valued vector with the dimensions where a cyclic boundary is used - 1: x-dimension, 2: y-dimension; 3: z-dimension; see details.
<code>names</code>	the names of the components; used to label the output, and for plotting.
<code>...</code>	additional arguments passed to function <code>stodes</code> . See note.

Details

This is the method of choice to find the steady-state for 3-dimensional models, that are only subjected to transport between adjacent layers.

Based on the dimension of the problem, the method first calculates the sparsity pattern of the Jacobian, under the assumption that transport is only occurring between adjacent layers. Then `stodes` is called to find the steady-state.

In some cases, a cyclic boundary condition exists. This is when the first boxes in x-, y-, or z-direction interact with the last boxes. In this case, there will be extra non-zero fringes in the Jacobian which need to be taken into account. The occurrence of cyclic boundaries can be toggled on by specifying argument `cyclicBnd`. For instance, `cyclicBnd = 1` indicates that a cyclic boundary is required only for the x-direction, whereas `cyclicBnd = c(1,2)` imposes a cyclic boundary for both x- and y-direction. The default is no cyclic boundaries.

As `stodes` is used, it will probably be necessary to specify the length of the real work array, `lrw`.

Although a reasonable guess of `lrw` is made, it may occur that this will be too low. In this case, `steady.3D` will return with an error message telling the size of the work array actually needed. In the second try then, set `lrw` equal to this number.

As `stodes` is used, it will probably be necessary to specify the length of the real work array, `lrw`.

Although a reasonable guess of `lrw` is made, it may occur that this will be too low. In this case, `steady.2D` will return with an error message telling that there was insufficient storage. In the second try then, increase `lrw`. you may need to experiment to find suitable value. The smaller the better.

The error message that says to increase `lrw` may look like this:

```
In stodes(y = y, time = time, func = func, parms = parms, nnz = c(nspec,
insufficient storage in nnfc
```

See `stodes` for the additional options.

Value

A list containing

`y` a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations.
 ... the "global" values returned.

The output will have the attribute `steady`, which returns `TRUE`, if steady-state has been reached and the attribute

`precis` with the precision attained during each iteration. Another attribute, called `dims` returns a.o. the length of the work array actually required. This can be specified with input argument `lrw`. See note and first example.

Note

It is advisable though not mandatory to specify BOTH `nspec` and `dims`. In this case, the solver can check whether the input makes sense (as `nspec*dims[1]*dims[2]*dims[3] = length(y)`) do NOT use this method for problems that are not 3D.

It is likely that the estimated length of the work array (argument `lrw`), required for the solver `stodes` will be too small. If that is the case, the solver will return with an error saying to increase `lrw`. The current value of the work array can be found via the attributes of the output. See first example.

```

steady.band

Steady-state solver for ordinary differential equations; assumes a banded jacobian

Description

Estimates the steady-state condition for a system of ordinary differential equations.

Assumes a banded jacobian matrix.

Usage

```
steady.band(y, time = 0, func, parms = NULL,
           nspec = NULL, bandup = nspec, banddown = nspec, ...)
```

Arguments

y	the initial guess of (state) values for the ODE system, a vector. If y has a name attribute, the names will be used to label the output matrix.
time	time for which steady-state is wanted; the default is time=0.
func	either an R-function that computes the values of the derivatives in the ode system (the model definition) at time time, or a character string giving the name of a compiled function in a dynamically loaded shared library. If func is an R-function, it must be defined as: <code>yprime = func(t, y, parms, ...)</code> . t is the current time point in the integration, y is the current estimate of the variables in the ODE system. If the initial values y has a names attribute, the names will be

available inside `func`. `parms` is a vector or list of parameters; ... (optional) are any other arguments passed to the function.

The return value of `func` should be a list, whose first element is a vector containing the derivatives of `y` with respect to `time`, and whose next elements are global values whose steady-state value is also required.

The derivatives should be specified in the same order as the state variables `y`.

<code>parms</code>	parameters passed to <code>func</code> .
<code>nspec</code>	the number of <i>*species*</i> (components) in the model.
<code>bandup</code>	the number of nonzero bands above the Jacobian diagonal.
<code>banddown</code>	the number of nonzero bands below the Jacobian diagonal.
<code>...</code>	additional arguments passed to function <code>stode</code> .

Details

This is the method of choice for single-species 1-D models.

For multi-species 1-D models, this method can only be used if the state variables are arranged per box, per species (e.g. `A[1],B[1],A[2],B[2],A[3],B[3],...` for species A, B).

Usually a 1-D **model** function will have the species arranged as `A[1],A[2],A[3],...,B[1],B[2],B[3],...` in this case, use `steady.1D`

Value

A list containing

<code>y</code>	a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. If <code>y</code> has a <code>names</code> attribute, it will be used to label the output values.
<code>...</code>	the number of "global" values returned.

The output will have the attribute `steady`, which returns `TRUE`, if steady-state has been reached and the attribute `precis` with the precision attained during each iteration.

stode	<i>Iterative steady-state solver for ordinary differential equations (ODE) and a full or banded Jacobian.</i>
-------	---

Description

Estimates the steady-state condition for a system of ordinary differential equations (ODE) written in the form:

$$dy/dt = f(t, y)$$

i.e. finds the values of y for which $f(t, y) = 0$.

Uses a newton-raphson method, implemented in Fortran 77.

The system of ODE's is written as an R function or defined in compiled code that has been dynamically loaded.

Usage

```

stode(y, time = 0, func, parms = NULL,
      rtol = 1e-6, atol = 1e-8, ctol = 1e-8,
      jacfunc = NULL, jactype = "fullint", verbose = FALSE,
      bandup = 1, banddown = 1, positive = FALSE,
      maxiter = 100, ynames = TRUE,
      dllname = NULL, initfunc = dllname, initpar = parms,
      rpar = NULL, ipar = NULL, nout = 0, outnames = NULL,
      forcings = NULL, initforc = NULL, fcontrol = NULL, ...)

```

Arguments

y	the initial guess of (state) values for the ode system, a vector. If y has a name attribute, the names will be used to label the output matrix.
time	time for which steady-state is wanted; the default is time=0.

func	<p>either a user-supplied function that computes the values of the derivatives in the ode system (the <i>model definition</i>) at time <code>time</code>, or a character string giving the name of a compiled function in a dynamically loaded shared library.</p> <p>If <code>func</code> is a user-supplied function, it must be called as: <code>yprime = func(t, y, parms, ...)</code>. <code>t</code> is the time point at which the steady-state is wanted, <code>y</code> is the current estimate of the variables in the ode system. If the initial values <code>y</code> has a <code>names</code> attribute, the names will be available inside <code>func</code>. <code>parms</code> is a vector of parameters (which may have a <code>names</code> attribute).</p> <p>The return value of <code>func</code> should be a list, whose first element is a vector containing the derivatives of <code>y</code> with respect to <code>time</code>, and whose next elements (possibly with a <code>names</code> attribute) are global values that are required as output.</p> <p>The derivatives should be specified in the same order as the state variables <code>y</code>.</p> <p>If <code>func</code> is a string, then <code>dllname</code> must give the name of the shared library (without extension) which must be loaded before <code>stode()</code> is called. see Details for more information.</p>
parms	other parameters passed to <code>func</code> and <code>jacfunc</code> .
rtol	relative error tolerance, either a scalar or a vector, one value for each <code>y</code> .
atol	absolute error tolerance, either a scalar or a vector, one value for each <code>y</code> .
ctol	if between two iterations, the maximal change in <code>y</code> is less than this amount, steady-state is assumed to be reached.
jacfunc	<p>if not NULL, either a user-supplied R function that estimates the Jacobian of the system of differential equations $dy(i)/dy(j)$, or a character string giving the name of a compiled function in a dynamically loaded shared library as provided in <code>dllname</code>. In some circumstances, supplying <code>jacfunc</code> can speed up the computations. The R calling sequence for <code>jacfunc</code> is identical to that of <code>func</code>.</p> <p>If the Jacobian is a full matrix, <code>jacfunc</code> should return a matrix $dydot/dy$, where the ith row contains the derivative of dy_i/dt with respect to y_j, or a vector containing the matrix elements by columns (the way R and Fortran store matrices).</p> <p>If the Jacobian is banded, <code>jacfunc</code> should return a matrix containing only the nonzero bands of the jacobian, ($dydot/dy$), rotated row-wise.</p>
jactype	the structure of the Jacobian, one of "fullint", "fullusr", "bandusr", or "bandint" - either full or banded and estimated internally or by the user.
verbose	if TRUE: full output to the screen, e.g. will output the steady-state settings.
bandup	number of non-zero bands above the diagonal, in case the Jacobian is banded.
banddown	number of non-zero bands below the diagonal, in case the jacobian is banded.
positive	either a logical or a vector with indices of the state variables that have to be non-negative; if TRUE, all state variables <code>y</code> are forced to be non-negative numbers.
maxiter	maximal number of iterations during one call to the solver.\
ynames	if FALSE: names of state variables are not passed to function <code>func</code> ; this may speed up the simulation especially for multi-D models.
dllname	a string giving the name of the shared library (without extension) that contains all the compiled function or subroutine definitions referred to in <code>func</code> and <code>jacfunc</code> .

<code>initfunc</code>	if not NULL, the name of the initialisation function (which initialises values of parameters), as provided in 'dllname'. See details.
<code>initpar</code>	only when 'dllname' is specified and an initialisation function <code>initfunc</code> is in the dll: the parameters passed to the initialiser, to initialise the common blocks (FORTRAN) or global variables (C, C++).
<code>rpar</code>	only when 'dllname' is specified: a vector with double precision values passed to the dll-functions whose names are specified by <code>func</code> and <code>jacfunc</code> .
<code>ipar</code>	only when 'dllname' is specified: a vector with integer values passed to the dll-functions whose names are specified by <code>func</code> and <code>jacfunc</code> .
<code>nout</code>	only used if 'dllname' is specified and the model is defined in compiled code: the number of output variables calculated in the compiled function <code>func</code> , present in the shared library. Note: it is not automatically checked whether this is indeed the number of output variables calculated in the dll - you have to perform this check in the code - see package vignette.
<code>outnames</code>	only used if 'dllname' is specified and <code>nout > 0</code> : the names of output variables calculated in the compiled function <code>func</code> , present in the shared library.
<code>forcings</code>	only used if 'dllname' is specified: a vector with the forcing function values, or a list with the forcing function data sets, each present as a two-columned matrix, with (time,value); interpolation outside the interval $[\min(\text{times}), \max(\text{times})]$ is done by taking the value at the closest data extreme. This feature is here for compatibility with models defined in compiled code from package <code>deSolve</code> ; see <code>deSolve</code> 's package vignette "compiledCode".
<code>initforc</code>	if not NULL, the name of the forcing function initialisation function, as provided in 'dllname'. It MUST be present if <code>forcings</code> has been given a value. See <code>deSolve</code> 's package vignette "compiledCode".
<code>fcontrol</code>	A list of control parameters for the forcing functions. See <code>deSolve</code> 's package vignette "compiledCode".
<code>...</code>	additional arguments passed to <code>func</code> and <code>jacfunc</code> allowing this to be a generic function.

Details

The work is done by a Fortran 77 routine that implements the Newton-Raphson method. It uses code from LINPACK.

The form of the **Jacobian** can be specified by `jactype` which can take the following values:

- `jactype = "fullint"` : a full jacobian, calculated internally by the solver, the default.
- `jactype = "fullusr"` : a full jacobian, specified by user function `jacfunc`.
- `jactype = "bandusr"` : a banded jacobian, specified by user function `jacfunc`; the size of the bands specified by `bandup` and `banddown`.
- `jactype = "bandint"` : a banded jacobian, calculated by the solver; the size of the bands specified by `bandup` and `banddown`.

if `jactype = "fullusr"` or `"bandusr"` then the user must supply a subroutine `jacfunc`.

The input parameters `rtol`, `atol` and `ctol` determine the **error control** performed by the solver.

The solver will control the vector \mathbf{e} of estimated local errors in \mathbf{y} , according to an inequality of the form $\max\text{-norm}(\mathbf{e}/\mathbf{ewt}) \leq 1$, where \mathbf{ewt} is a vector of positive error weights. The values of \mathbf{rtol} and \mathbf{atol} should all be non-negative. The form of \mathbf{ewt} is:

$$\mathbf{rtol} \times \text{abs}(\mathbf{y}) + \mathbf{atol}$$

where multiplication of two vectors is element-by-element.

In addition, the solver will stop if between two iterations, the maximal change in the values of \mathbf{y} is less than \mathbf{ctol} .

Models may be defined in compiled C or Fortran code, as well as in R.

If `func` or `jacfunc` are a string, then they are assumed to be compiled code.

In this case, `dllname` must give the name of the shared library (without extension) which must be loaded before `stode()` is called.

See vignette("rooSolve") for how a model has to be specified in compiled code. Also, vignette("compiledCode") from package **deSolve** contains examples of how to do this.

If `func` is a user-supplied **R-function**, it must be called as: `yprime = func(t, y, parms,...)`. `t` is the time at which the steady-state should be estimated, `y` is the current estimate of the variables in the ode system. The return value of `func` should be a list, whose first element is a vector containing the derivatives of `y` with respect to time, and whose next elements contains output variables whose values at steady-state are also required.

An example is given below:

```
model<-function(t,y,parms)
{
  with (as.list(c(y,parms)),{
    Min      = r*OM
    oxicmin   = Min*(O2/(O2+ks))
    anoxicmin = Min*(1-O2/(O2+ks))* S04/(S04+ks2)
    dOM      = Flux - oxicmin - anoxicmin
    dO2      = -oxicmin      -2*rox*HS*(O2/(O2+ks)) + D*(B02-O2)
    dS04     = -0.5*anoxicmin +rox*HS*(O2/(O2+ks)) + D*(BS04-S04)
    dHS      = 0.5*anoxicmin -rox*HS*(O2/(O2+ks)) + D*(BHS-HS)

    list(c(dOM,dO2,dS04,dHS),SumS=S04+HS)
  })
}
```

This model can be solved as follows:

```
parms <- c(D=1,Flux=100,r=0.1,rox =1,
ks=1,ks2=1,B02=100,BS04=10000,BHS = 0)
```

```
y<-c(OM=1,O2=1,S04=1,HS=1)
ST <- stode(y=y,func=model,parms=parms,pos=TRUE))
```

Value

A list containing

`y` a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. If `y` has a `names` attribute, it will be used to label the output values.

`...` the number of "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached and the attribute `precis` with an estimate of the precision attained during each iteration, the mean absolute rate of change ($\text{sum}(\text{abs}(\text{dy}))/n$).

Note

The implementation of `stode` and substantial parts of the help file is similar to the implementation of the integration routines (e.g. `lsode`) from package `deSolve`.

## =====
## Example 3. Solving a system of linear equations
## =====

# this example is included to demonstrate how to use the "jactype" option.
# (and that stode is quite efficient).

A <- matrix(nrow = 500, ncol = 500, runif(500*500))
B <- 1:500

# this is how one would solve this in R
print(system.time(X1 <- solve(A, B)))

# to use stode:
# 1. create a function that receives the current estimate of x
# and that returns the difference A%%x-B, as a list:

fun <- function (t, x, p) # t and p are dummies here...
  list(A%%x-B)

# 2. jfun returns the Jacobian: here this equals "A"
jfun <- function (t, x, p) # all input parameters are dummies
  A

# 3. solve with jactype="fullusr" (a full Jacobian, specified by user)
print (system.time(
  X <- stode(y = 1:500, func = fun, jactype = "fullusr", jacfunc = jfun)
))

# the results are the same (within precision)
sum((X1-X$y)^2)

```

stodes

Steady-state solver for ordinary differential equations (ODE) with a sparse jacobian.

Description

Estimates the steady-state condition for a system of ordinary differential equations (ODE) in the form:

$$dy/dt = f(t, y)$$

and where the jacobian matrix df/dy has an arbitrary sparse structure.

Uses a newton-raphson method, implemented in Fortran.

The system of ODE's is written as an R function or defined in compiled code that has been dynamically loaded.

Usage

```
stodes(y, time = 0, func, parms = NULL, rtol = 1e-6, atol = 1e-8,
       ctol = 1e-8, sparsetype = "sparseint", verbose = FALSE,
       nnz = NULL, inz = NULL, lrw = NULL, ngp = NULL,
       positive = FALSE, maxiter = 100, ynames = TRUE,
       dllname = NULL, initfunc = dllname, initpar = parms,
       rpar = NULL, ipar = NULL, nout = 0, outnames = NULL,
       forcings = NULL, initforc = NULL, fcontrol = NULL,
       spmethod = "yale", control = NULL,...)
```

Arguments

y	the initial guess of (state) values for the ode system, a vector. If y has a name attribute, the names will be used to label the output matrix.
time	time for which steady-state is wanted; the default is time=0.
func	<p>either a user-supplied function that computes the values of the derivatives in the ode system (the <i>model definition</i>) at time time, or a character string giving the name of a compiled function in a dynamically loaded shared library.</p> <p>If func is a user-supplied function, it must be called as: <code>yprime = func(t, y, parms)</code>. t is the time point at which the steady-state is wanted, y is the current estimate of the variables in the ode system. If the initial values y has a names attribute, the names will be available inside func. parms is a vector of parameters (which may have a names attribute).</p> <p>The return value of func should be a list, whose first element is a vector containing the derivatives of y with respect to time, and whose next elements (possibly with a names attribute) are global values that are required as output.</p> <p>The derivatives should be specified in the same order as the state variables y.</p> <p>If func is a string, then dllname must give the name of the shared library (without extension) which must be loaded before stodes() is called. see Details for more information.</p>
parms	other parameters passed to func.
rtol	relative error tolerance, either a scalar or a vector, one value for each y.
atol	absolute error tolerance, either a scalar or a vector, one value for each y.
ctol	if between two iterations, the maximal change in y is less than this amount, steady-state is assumed to be reached.
sparsetype	the sparsity structure of the Jacobian, one of "sparseint" or "sparseusr", "sparsejan", ..., The sparsity can be estimated internally by stodes (first option) or given by the user (last two). See details.
verbose	if TRUE: full output to the screen, e.g. will output the steady-state settings.

nnz	<p>the number of nonzero elements in the sparse Jacobian (if this is unknown, use an estimate); If NULL, a guess will be made, and if not sufficient, stodes will return with a message indicating the size actually required.</p> <p>If a solution is found, the minimal value of nnz actually required is returned by the solver (1st element of attribute dims).</p>
inz	<p>if sparsetype equal to "sparseusr", a two-columned matrix with the (row, column) indices to the nonzero elements in the sparse Jacobian. If sparsetype = "sparsejan", a vecotr with the elements ian followed by he elements jan as used in the stodes code. See details. In all other cases, ignored. If inz is NULL, the sparsity will be determined by stodes.</p>
lrw	<p>the length of the work array of the solver; due to the sparsicity, this cannot be readily predicted. If NULL, a guess will be made, and if not sufficient, stodes will return with a message indicating that lrw should be increased. Therefore, some experimentation may be necessary to estimate the value of lrw.</p> <p>If a solution is found, the minimal value of lrw actually required is returned by the solver (3rd element of attribute dims).</p> <p>In case of an error induced by a too small value of lrw, its value can be assessed by the attributes()\$dims value.</p>
ngp	<p>number of groups of independent state variables. Due to the sparsicity, this cannot be readily predicted. If NULL, a guess will be made, and if not sufficient, stodes will return with a message indicating the size actually required. Therefore, some experimentation may be necessary to estimate the value of ngp</p> <p>If a solution is found, the minimal value of ngp actually required is returned by the solver (2nd element of attribute dims).</p>
positive	<p>either a logical or a vector with indices of the state variables that have to be non-negative; if TRUE, the state variables are forced to be non-negative numbers.</p>
maxiter	<p>maximal number of iterations during one call to the solver.</p>
yname	<p>if FALSE: names of state variables are not passed to function func ; this may speed up the simulation especially for multi-D models.</p>
dllname	<p>a string giving the name of the shared library (without extension) that contains all the compiled function or subroutine definitions referred to in func.</p>
initfunc	<p>if not NULL, the name of the initialisation function (which initialises values of parameters), as provided in 'dllname'. See details.</p>
initpar	<p>only when 'dllname' is specified and an initialisation function initfunc is in the dll: the parameters passed to the initialiser, to initialise the common blocks (FORTRAN) or global variables (C, C++).</p>
rpar	<p>only when 'dllname' is specified: a vector with double precision values passed to the dll-functions whose names are specified by func.</p>
ipar	<p>only when 'dllname' is specified: a vector with integer values passed to the dll-functions whose names are specified by func.</p>
nout	<p>only used if 'dllname' is specified: the number of output variables calculated in the compiled function func, present in the shared library.</p>
outnames	<p>only used if 'dllname' is specified and nout > 0: the names of output variables calculated in the compiled function func, present in the shared library.</p>

<code>spmethod</code>	the sparse method to be used, one of "yale", "ilut", "ilutp". The default uses the yale sparse matrix solver; the other use preconditioned GMRES (generalised minimum residual method) solvers from FORTRAN package sparsekit. <code>ilut</code> stands for incomplete LU factorisation with threshold (or tolerances, <code>droptol</code>); the "p" in <code>ilutp</code> stands for pivoting.
<code>control</code>	only used if <code>spmethod</code> not equal to "yale", a list with the control options of the preconditioned solvers. The default is <code>list(droptol = 1e-3, permtol = 1e-3, fillin = 10, droptol</code> is the tolerance in <code>ilut</code> , <code>ilutp</code> to decide when to drop a value. <code>permtol</code> is used in <code>ilutp</code> , to decide whether or not to permute variables. See Saad 1994, the manual of sparsekit and Saad 2003, chapter 10 for details.
<code>forcings</code>	only used if 'dllname' is specified: a vector with the forcing function values, or a list with the forcing function data sets, each present as a two-columned matrix, with (time,value); interpolation outside the interval [<code>min(times)</code> , <code>max(times)</code>] is done by taking the value at the closest data extreme. This feature is here for compatibility with models defined in compiled code from package <code>deSolve</code> ; see <code>deSolve</code> 's package vignette "compiledCode".
<code>initforc</code>	if not NULL, the name of the forcing function initialisation function, as provided in 'dllname'. It MUST be present if <code>forcings</code> has been given a value. See <code>deSolve</code> 's package vignette "compiledCode".
<code>fcontrol</code>	A list of control parameters for the forcing functions. See <code>deSolve</code> 's package vignette "compiledCode".
<code>...</code>	additional arguments passed to <code>func</code> allowing this to be a generic function.

Details

The work is done by a Fortran 77 routine that implements the Newton-Raphson method.

`stodes` is to be used for problems, where the Jacobian has a sparse structure.

There are several choices for the sparsity specification, selected by argument `sparsetype`.

- `sparsetype = "sparseint"`. The sparsity is estimated by the solver, based on numerical differences. In this case, it is advisable to provide an estimate of the number of non-zero elements in the Jacobian (`nnz`). This value can be approximate; upon return the number of nonzero elements actually required will be known (1st element of attribute `dims`). In this case, `inz` need not be specified.
- `sparsetype = "sparseusr"`. The sparsity is determined by the user. In this case, `inz` should be a matrix, containing indices (row, column) to the nonzero elements in the Jacobian matrix. The number of nonzeros `nnz` will be set equal to the number of rows in `inz`.
- `sparsetype = "sparsejan"`. The sparsity is also determined by the user. In this case, `inz` should be a vector, containing the `ian` and `jan` elements of the sparse storage format, as used in the sparse solver. Elements of `ian` should be the first `n+1` elements of this vector, and contain the starting locations in `jan` of columns 1.. `n`. `jan` contains the row indices of the nonzero locations of the jacobian, reading in columnwise order. The number of nonzeros `nnz` will be set equal to the length of `inz` - (`n+1`).
- `sparsetype = "1D", "2D", "3D"`. The sparsity is estimated by the solver, based on numerical differences. Assumes finite differences in a 1D, 2D or 3D regular grid - used by functions `ode.1D`, `ode.2D`, `ode.3D`. Similar are `"2Dmap"`, and `"3Dmap"`, which also include a mapping variable (passed in `nnz`).

The Jacobian itself is always generated by the solver (i.e. there is no provision to provide an analytic Jacobian).

This is done by perturbing simultaneously a combination of state variables that do not affect each other.

This significantly reduces computing time. The number of groups with independent state variables can be given by `ngp`.

The input parameters `rtol`, `atol` and `ctol` determine the **error control** performed by the solver. See help for `stode` for details.

Models may be defined in compiled C or Fortran code, as well as in R. See package vignette for details on how to write models in compiled code.

When the `spmethod` equals `ilut` or `ilutp`, a number of parameters can be specified in argument `control`. They are:

`fillin`, the fill-in parameter. Each row of L and each row of U will have a maximum of `lfil` elements (excluding the diagonal element). `lfil` must be ≥ 0 .

`droptol`, sets the threshold for dropping small terms in the factorization.

When `ilutp` is chosen the following arguments can also be specified:

`permtol` = tolerance ratio used to determine whether or not to permute two columns. At step `i` columns `i` and `j` are permuted when $\text{abs}(a(i,j)) * \text{permtol} > \text{abs}(a(i,i))$ [0 \rightarrow never permute; good values 0.1 to 0.01]

`lenplufac` = sets the working array - increase its value if a warning.

Value

A list containing

`y` a vector with the state variable values from the last iteration during estimation of steady-state condition of the system of equations. If `y` has a `names` attribute, it will be used to label the output values.

... the number of "global" values returned.

The output will have the attribute `steady`, which returns TRUE, if steady-state has been reached and the attribute `precis` with an estimate of the precision attained during each iteration, the mean absolute rate of change $(\text{sum}(\text{abs}(\text{dy}))/n)$.

# the size of lrw is in the attributes()$dims vector.
attributes(ss)

```

uniroot.all

Finds many (all) roots of one equation within an interval

Description

The function `uniroot.all` searches the interval from lower to upper for several roots (i.e., zero's) of a function `f` with respect to its first argument.

Usage

```

uniroot.all(f, interval, lower = min(interval), upper = max(interval),
            tol = .Machine$double.eps^0.2, maxiter = 1000, n = 100, ...)

```

Arguments

<code>f</code>	the function for which the root is sought.
<code>interval</code>	a vector containing the end-points of the interval to be searched for the root.
<code>lower</code>	the lower end point of the interval to be searched.
<code>upper</code>	the upper end point of the interval to be searched.
<code>tol</code>	the desired accuracy (convergence tolerance).
<code>maxiter</code>	the maximum number of iterations.
<code>n</code>	number of subintervals in which the root is sought.
<code>...</code>	additional named or unnamed arguments to be passed to <code>f</code> (but beware of partial matching to other arguments).

Details

`f` will be called as `f(x, ...)` for a numeric value of `x`.

Run `demo(Jacobandroots)` for an example of the use of `uniroot.all` for steady-state analysis.

See also second example of [gradient](#) This example is discussed in the book by Soetaert and Herman (2009).

Value

a vector with the roots found in the interval

Note

The function calls `uniroot`, the basic R-function.

It is not guaranteed that all roots will be recovered.

This will depend on `n`, the number of subintervals in which the interval is divided.

If the function "touches" the X-axis (i.e. the root is a saddle point), then this root will generally not be retrieved. (but chances of this are pretty small).

Whereas `uniroot` passes values one at a time to the function, `uniroot.all` passes a vector of values to the function. Therefore `f` should be written such that it can handle a vector of values. See last example.

[uniroot](#) for more information about input.

Examples

```
## =====
## Mathematical examples
## =====

# a well-behaved case...
fun <- function (x) cos(2*x)^3

curve(fun(x), 0, 10, main = "uniroot.all")

All <- uniroot.all(fun, c(0, 10))
points(All, y = rep(0, length(All)), pch = 16, cex = 2)

# a difficult case...
f <- function (x) 1/cos(1+x^2)
AA <- uniroot.all(f, c(-5, 5))
curve(f(x), -5, 5, n = 500, main = "uniroot.all")
points(AA, rep(0, length(AA)), col = "red", pch = 16)

f(AA) # !!!
