

Package ‘FRK’

October 13, 2017

Type Package

Title Fixed Rank Kriging

Version 0.1.6

Date 2017-05-25

Maintainer Andrew Zammit-Mangion <andrewzm@gmail.com>

VignetteBuilder knitr

Description Fixed Rank Kriging is a tool for spatial/spatio-temporal modelling and prediction with large datasets. The approach, discussed in Cressie and Johannesson (2008) <DOI:10.1111/j.1467-9868.2007.00633.x>, decomposes the field, and hence the covariance function, using a fixed set of n basis functions, where n is typically much smaller than the number of data points (or polygons) m . The method naturally allows for non-stationary, anisotropic covariance functions and the use of observations with varying support (with known error variance). The projected field is a key building block of the Spatial Random Effects (SRE) model, on which this package is based. The package FRK provides helper functions to model, fit, and predict using an SRE with relative ease.

FRK-package

*Fixed Rank Kriging***Description**

Fixed Rank Kriging is a tool for spatial/spatio-temporal modelling and prediction with large datasets. The approach, discussed in Cressie and Johannesson (2008), decomposes the field, and hence the covariance function, using a fixed set of n basis functions, where dimension n is typically much smaller than the number of data points (or polygons) m . The method naturally allows for non-stationary, anisotropic covariance functions and the use of observations with varying support (with known error variance). The dimension-reduced field is a key building block of the Spatial Random Effects (SRE) model, upon which this package is based. The package FRK provides helper functions to model, fit, and predict using an SRE with relative ease. Reference: Cressie, N. and Johannesson, G. (2008) <DOI:10.1111/j.1467-9868.2007.00633.x>.

AIRS_05_2003

*AIRS data for May 2003***Description**

Mid-tropospheric CO₂ measurements from the Atmospheric InfraRed Sounder (AIRS). The data are measurements between 60 degrees S and 90 degrees N at roughly 1:30 pm local time on 1 May through to 15 May 2003. (AIRS does not release data below 60 degrees S.)

Usage

AIRS_05_2003

Format

A data frame with 209631 rows and 7 variables:

year year of retrieval**month** month of retrieval**day** day of retrieval**lon** longitude coordinate of retrieval**lat** latitude coordinate of retrieval**co2avgret** CO₂ mole fraction retrieval in ppm**co2std** standard error of CO₂ retrieval in ppm**References**

Chahine, M. et al. (2006). AIRS: Improving weather forecasting and providing new data on greenhouse gases. *Bulletin of the American Meteorological Society* 87, 911–26.

 auto_basis

Automatic basis-function placement

Description

Generate automatically a set of local basis functions in the domain, and automatically prune in regions of sparse data.

Usage

```
auto_basis(manifold = plane(), data, regular = 1, nres = 3, prune = 0,
  max_basis = NULL, subsamp = 10000, type = c("bisquare", "Gaussian",
  "exp", "Matern32"), isea3h_lo = 2, bndary = NULL,
  scale_aperture = ifelse(is(manifold, "sphere"), 1, 1.25), verbose = 0L,
  ...)
```

Arguments

manifold	object of class manifold, for example, sphere or plane
data	object of class SpatialPointsDataFrame or SpatialPolygonsDataFrame containing the data on which basis-function placement is based, or a list of these; see details
regular	an integer indicating the number of regularly-placed basis functions at the first resolution. In two dimensions, this dictates the smallest number of basis functions in a row or column at the coarsest resolution. If regular=0, an irregular grid is used, one that is based on the triangulation of the domain with increased mesh density in areas of high data density; see details
nres	the number of basis-function resolutions to use
prune	a threshold parameter that dictates when a basis function is considered irrelevant or unidentifiable, and thus removed; see details
max_basis	maximum number of basis functions. This overrides the parameter nres
subsamp	the maximum amount of data points to consider when carrying out basis-function placement: these data objects are randomly sampled from the full dataset. Keep this number fairly high (on the order of 10^5), otherwise fine-resolution basis functions may be spuriously removed
type	the type of basis functions to use; see details
isea3h_lo	if manifold = sphere(), this argument dictates which ISEA3H resolution is the coarsest one that should be used for the first resolution
bndary	a matrix containing points containing the boundary. If regular == 0 this can be used to define a boundary in which irregularly-spaced basis functions are placed
scale_aperture	the aperture (in the case of the bisquare, but similar interpretation for other basis) width of the basis function is the minimum distance between all the basis function centroids multiplied by scale_aperture. Typically this ranges between 1 and 1.5 and is defaulted to 1 on the sphere and 1.25 on the other manifolds.

verbose	a logical variable indicating whether to output a summary of the basis functions created or not
...	unused

Details

This function automatically places basis functions within the domain of interest. If the domain is a plane or the real line, then the object data is used to establish the domain boundary.

The argument type can be either “Gaussian”, in which case

$$\phi(u) = \exp\left(-\frac{\|u\|^2}{2\sigma^2}\right),$$

“bisquare”, in which case

$$\phi(u) = \left(1 - \left(\frac{\|u\|}{R}\right)^2\right)^2 I(\|u\| < R),$$

“exp”, in which case

$$\phi(u) = \exp\left(-\frac{\|u\|}{\tau}\right),$$

or “Matern32”, in which case

$$\phi(u) = \left(1 + \frac{\sqrt{3}\|u\|}{\kappa}\right) \exp\left(-\frac{\sqrt{3}\|u\|}{\kappa}\right),$$

where the parameters σ , R , τ and κ are scale arguments.

If the manifold is the real line, the basis functions are placed regularly inside the domain, and the number of basis functions at the coarsest resolution is dictated by the integer parameter `regular` which has to be greater than zero. On the real line, each subsequent resolution has twice as many basis functions. The scale of the basis function is set based on the minimum distance between the centre locations following placement. The scale is equal to the minimum distance if the type of basis function is Gaussian, exponential, or Matern32, and is equal to 1.5 times this value if the function is bisquare.

If the manifold is a plane, and `regular > 0`, then basis functions are placed regularly within the bounding box of data, with the smallest number of basis functions in each row or column equal to the value of `regular` in the coarsest resolution (note, this is just the smallest number of basis functions). Subsequent resolutions have twice the number of basis functions in each row or column. If `regular = 0`, then the function `INLA::inla.nonconvex.hull` is used to construct a (non-convex) hull around the data. The buffer and smoothness of the hull is determined by the parameter `convex`. Once the domain boundary is found, `INLA::inla.mesh.2d` is used to construct a triangular mesh such that the node vertices coincide with data locations, subject to some minimum and maximum triangular-side-length constraints. The result is a mesh that is dense in regions of high data density and not dense in regions of sparse data. Even basis functions are irregularly placed, the scale is taken to be a function of the minimum distance between basis function centres, as detailed above. This may be changed in a future revision of the package.

If the manifold is the surface of a sphere, then basis functions are placed on the centroids of the discrete global grid (DGG), with the first basis resolution corresponding to the third resolution of

the DGG (ISEA3H resolution 2, which yields 92 basis functions globally). It is not recommended to go above `nres == 3` (ISEA3H resolutions 2–4) for the whole sphere; `nres=3` yields a total of 1176 basis functions. Up to ISEA3H resolution 6 is available with FRK; for finer resolutions; please install `dggrids` from <https://github.com/andrewzm/dggrids> using `devtools`.

Basis functions that are not influenced by data points may hinder convergence of the EM algorithm when `K_type = ``unstructured```, since the associated hidden states are, by and large, unidentifiable. We hence provide a means to automatically remove such basis functions through the parameter `prune`. The final set only contains basis functions for which the column sums in the associated matrix S (which, recall, is the value/average of the basis functions at/over the data points/polygons) is greater than `prune`. If `prune == 0`, no basis functions are removed from the original design.

Examples

```
## Not run:
library(sp)
library(ggplot2)

### Create a synthetic dataset
set.seed(1)
d <- data.frame(lon = runif(n=1000,min = -179, max = 179),
                lat = runif(n=1000,min = -90, max = 90),
                z = rnorm(5000))
coordinates(d) <- ~lon + lat
proj4string(d)=CRS("+proj=longlat +ellps=sphere")

### Now create basis functions over sphere
G <- auto_basis(manifold = sphere(),data=d,
               nres = 2,prune=15,
               type = "bisquare",
               subsamp = 20000)

### Plot
\dontrun{show_basis(G,draw_world())}

## End(Not run)
```

auto_BAUs

Automatic BAU generation

Description

This function calls the generic function `auto_BAU` (not exported) after a series of checks and is the easiest way to generate a set of Basic Areal Units (BAUs) on the manifold being used; see details.

Usage

```
auto_BAUs(manifold, type = NULL, cellsize = NULL, isea3h_res = NULL,
          data = NULL, nonconvex_hull = TRUE, convex = -0.05, tunit = NULL,
          xlims = NULL, ylims = NULL, ...)
```

Arguments

manifold	object of class manifold
type	either “grid” or “hex”, indicating whether gridded or hexagonal BAUs should be used
cellsize	denotes size of gridcell when type = “grid”. Needs to be of length 1 (square-grid case) or a vector of length dimensions(manifold) (rectangular-grid case)
isea3h_res	resolution number of the isea3h DGGRID cells for when type is “hex” and manifold is the surface of a sphere
data	object of class SpatialPointsDataFrame, SpatialPolygonsDataFrame, STIDF, or STFDF. Provision of data implies that the domain is bounded, and is thus necessary when the manifold is a <code>real_line</code> , <code>plane</code> , or <code>STplane</code> , but is not necessary when the manifold is the surface of a sphere
nonconvex_hull	flag indicating whether to use INLA to generate a non-convex hull. Otherwise a convex hull is used
convex	convex parameter used for smoothing an extended boundary when working on a bounded domain (that is, when the object data is supplied); see details
tunit	temporal unit when requiring space-time BAUs. Can be either "secs", "mins", "hours" or "days"
xlims	limits of the horizontal axis (overrides automatic selection)
ylims	limits of the vertical axis (overrides automatic selection)
...	currently unused

Details

auto_BAUs constructs a set of Basic Areal Units (BAUs) used both for data pre-processing and for prediction. As such, the BAUs need to be of sufficiently fine resolution so that inferences are not affected due to binning.

Two types of BAUs are supported by FRK: “hex” (hexagonal) and “grid” (rectangular). In order to have a “grid” set of BAUs, the user should specify a cellsize of length one, or of length equal to the dimensions of the manifold, that is, of length 1 for `real_line` and of length 2 for the surface of a sphere and plane. When a “hex” set of BAUs is desired, the first element of `cellsize` is used to determine the side length by dividing this value by approximately 2. The argument `type` is ignored with `real_line` and “hex” is not available for this manifold.

If the object data is provided, then automatic domain selection may be carried out by employing the INLA function `inla.nonconvex.hull`, which finds a (non-convex) hull surrounding the data points (or centroids of the data polygons). This domain is extended and smoothed using the parameter `convex`. The parameter `convex` should be negative, and a larger absolute value for `convex` results in a larger domain with smoother boundaries (note that INLA was not available on CRAN at the time of writing).

Examples

```
## First a 1D example
library(sp)
set.seed(1)
```

```

data <- data.frame(x = runif(10)*10, y = 0, z = runif(10)*10)
coordinates(data) <- ~x+y
Grid1D_df <- auto_BAUs(manifold = real_line(),
                      cellsize = 1,
                      data=data)
## Not run: spplot(Grid1D_df)

## Now a 2D example
data(meuse)
coordinates(meuse) = ~x+y # change into an sp object
if(require(INLA)) {
  ## Grid BAUs
  GridPols_df <- auto_BAUs(manifold = plane(),
                          cellsize = 200,
                          type = "grid",
                          data = meuse,
                          convex=-0.05)
  ## Not run: plot(GridPols_df)

  ## Hex BAUs
  HexPols_df <- auto_BAUs(manifold = plane(),
                          cellsize = 200,
                          type = "hex",
                          data = meuse,
                          convex=-0.05)
  ## Not run: plot(HexPols_df)
}

```

Basis_obj-class

Basis functions

Description

An object of class `Basis` contains the basis functions used to construct the matrix S in FRK. It contains five slots, described below.

Details

Basis functions are a central component of FRK, and the package is designed to work with user-defined specifications of these. For convenience, however, several functions are available to aid the user to construct a basis set for a given set of data points. Please see [auto_basis](#) for more details. The function [local_basis](#) helps the user construct a set of local basis functions (e.g., bisquare functions) from a collection of location and scale parameters.

Slots

`manifold` an object of class `manifold` that contains information on the manifold and the distance measure used on the manifold. See [manifold-class](#) for more details

`n` the number of basis functions in this set

`fn` a list of length `n`, with each item the function of a specific basis function

`pars` a list of parameters where the i -th item in the list contains the parameters of the i -th basis function, `fn[[i]]`

`df` a data frame containing other attributes specific to each basis function (for example the geometric centre of the local basis function)

BAUs_from_points	<i>Creates pixels around points</i>
------------------	-------------------------------------

Description

Takes a `SpatialPointsDataFrame` and converts it into `SpatialPolygonsDataFrame` by constructing a tiny (within machine tolerance) BAU around each `SpatialPoint`.

Usage

```
BAUs_from_points(obj, offset = 1e-10)

## S4 method for signature 'SpatialPoints'
BAUs_from_points(obj, offset = 1e-10)

## S4 method for signature 'ST'
BAUs_from_points(obj, offset = 1e-10)
```

Arguments

<code>obj</code>	object of class <code>SpatialPointsDataFrame</code>
<code>offset</code>	edge size of the mini-BAU (default 1e-10)

Details

This function allows users to mimic standard geospatial analysis where BAUs are not used. Since FRK is built on the concept of a BAU, this function constructs tiny BAUs around the observation and prediction locations that can be subsequently passed on to the functions SRE and FRK. With `BAUs_from_points`, the user supplies both the data and prediction locations accompanied with covariates.

Examples

```
library(sp)
opts_FRK$set("parallel",0L)
df <- data.frame(x = rnorm(10),
                 y = rnorm(10))
coordinates(df) <- ~x+y
BAUs <- BAUs_from_points(df)
```

data.frame<- *Basis-function data frame object*

Description

Tools for retrieving and manipulating the data frame within the Basis objects. Use the assignment `data.frame()`<- with care; no checks are made to make sure the data frame conforms with the object. Only use if you know what you're doing.

Usage

```
data.frame(x) <- value

## S4 method for signature 'Basis'
x$name

## S4 replacement method for signature 'Basis'
x$name <- value

## S4 replacement method for signature 'Basis'
data.frame(x) <- value

## S4 replacement method for signature 'TensorP_Basis'
data.frame(x) <- value

## S3 method for class 'Basis'
as.data.frame(x, ...)

## S3 method for class 'TensorP_Basis'
as.data.frame(x, ...)
```

Arguments

<code>x</code>	the object of class Basis we are assigning the new data to or retrieving data from
<code>value</code>	the new data being assigned to the Basis object
<code>name</code>	the field name to which values will be retrieved or assigned inside the Basis object's data frame
<code>...</code>	unused

Examples

```
G <- local_basis()
df <- data.frame(G)
print(df$res)
df$res <- 2
data.frame(G) <- df
```

df_to_SpatialPolygons *Convert data frame to SpatialPolygons*

Description

Convert data frame to SpatialPolygons object.

Usage

```
df_to_SpatialPolygons(df, keys, coords, proj)
```

Arguments

df	data frame containing polygon information, see details
keys	vector of variable names used to group rows belonging to the same polygon
coords	vector of variable names identifying the coordinate columns
proj	the projection of the SpatialPolygons object. Needs to be of class CRS

Details

Each row in the data frame `df` contains both coordinates and labels (or keys) that identify to which polygon the coordinates belong. This function groups the data frame according to keys and forms a `SpatialPolygons` object from the coordinates in each group. It is important that all rings are closed, that is, that the last row of each group is identical to the first row. Since keys can be of length greater than one, we identify each polygon with a new key by forming an MD5 hash made out of the respective keys variables that in themselves are unique (and therefore the hashed key is also unique). For lon-lat coordinates use `proj = CRS("+proj=longlat +ellps=sphere")`.

Examples

```
library(sp)
df <- data.frame(id = c(rep(1,4),rep(2,4)),
                 x = c(0,1,0,0,2,3,2,2),
                 y=c(0,0,1,0,0,1,1,0))
pols <- df_to_SpatialPolygons(df,"id",c("x","y"),CRS())
## Not run: plot(pols)
```

`dist-matrix`*Distance Matrix Computation from Two Matrices*

Description

This function extends `dist` to accept two arguments.

Usage

```
distR(x1, x2 = NULL)
```

Arguments

<code>x1</code>	matrix of size $N1 \times n$
<code>x2</code>	matrix of size $N2 \times n$

Details

Computes the distances between the coordinates in `x1` and the coordinates in `x2`. The matrices `x1` and `x2` do not need to have the same number of rows, but need to have the same number of columns (dimensions).

Value

Matrix of size $N1 \times N2$

Examples

```
A <- matrix(rnorm(50),5,10)
D <- distR(A,A[-3,])
```

`distance`*Compute distance*

Description

Compute distance using object of class `measure` or `manifold`.

Usage

```
distance(d, x1, x2 = NULL)
```

```
## S4 method for signature 'measure'
distance(d, x1, x2 = NULL)
```

```
## S4 method for signature 'manifold'
distance(d, x1, x2 = NULL)
```

Arguments

d	object of class measure or manifold
x1	first coordinate
x2	second coordinate

Examples

```
distance(sphere(),matrix(0,1,2),matrix(10,1,2))
distance(plane(),matrix(0,1,2),matrix(10,1,2))
```

distances	<i>Pre-configured distances</i>
-----------	---------------------------------

Description

Useful objects of class distance included in package.

Usage

```
measure(dist, dim)

Euclid_dist(dim = 2L)

gc_dist(R = NULL)

gc_dist_time(R = NULL)
```

Arguments

dist	a function taking two arguments x1, x2
dim	the dimension of the manifold (e.g., 2 for a plane)
R	great-circle radius

Details

Initialises an object of class measure which contains a function dist used for computing the distance between two points. Currently the Euclidean distance and the great-circle distance are included with FRK.

Examples

```
M1 <- measure(distR,2)
D <- distance(M1,matrix(rnorm(10),5,2))
```

draw_world	<i>Draw a map of the world with country boundaries.</i>
------------	---

Description

Layers a ggplot2 map of the world over the current ggplot2 object.

Usage

```
draw_world(g = ggplot() + theme_bw() + xlab("") + ylab(""),
           inc_border = TRUE)
```

Arguments

<code>g</code>	initial ggplot object
<code>inc_border</code>	flag indicating whether a map border should be drawn or not; see details.

Details

This function uses `ggplot2::map_data` in order to create a world map. Since, by default, this creates lines crossing the world at the $(-180,180)$ longitude boundary, function `.homogenise_maps` is used to split the polygons at this boundary into two. If `inc_border` is `TRUE`, then a border is drawn around the lon-lat space; this option is most useful for projections that do not yield rectangular plots (e.g., the sinusoidal global projection).

Examples

```
## Not run:
library(ggplot2)
draw_world(g = ggplot())
## End(Not run)
```

eval_basis	<i>Evaluate basis functions</i>
------------	---------------------------------

Description

Evaluate basis functions at points or average functions over polygons.

Usage

```
eval_basis(basis, s)

## S4 method for signature 'Basis,matrix'
eval_basis(basis, s)

## S4 method for signature 'Basis,SpatialPointsDataFrame'
eval_basis(basis, s)

## S4 method for signature 'Basis,SpatialPolygonsDataFrame'
eval_basis(basis, s)

## S4 method for signature 'Basis,STIDF'
eval_basis(basis, s)

## S4 method for signature 'TensorP_Basis,matrix'
eval_basis(basis, s)

## S4 method for signature 'TensorP_Basis,STIDF'
eval_basis(basis, s)

## S4 method for signature 'TensorP_Basis,STDF'
eval_basis(basis, s)
```

Arguments

basis	object of class Basis
s	object of class matrix, SpatialPointsDataFrame or SpatialPolygonsDataFrame containing the spatial locations/footprints

Details

This function evaluates the basis functions at isolated points, or averages the basis functions over polygons, for computing the matrix S . The latter operation is carried out using Monte Carlo integration with 1000 samples per polygon. When using space-time basis functions, the object must contain a field `t` containing a numeric representation of the time, for example, containing the number of seconds, hours, or days since the first data point.

Examples

```
library(sp)

### Create a synthetic dataset
set.seed(1)
d <- data.frame(lon = runif(n=1000,min = -179, max = 179),
                lat = runif(n=1000,min = -90, max = 90),
                z = rnorm(5000))
coordinates(d) <- ~lon + lat
proj4string(d)=CRS("+proj=longlat")
```

```
### Now create basis functions on sphere
G <- auto_basis(manifold = sphere(),data=d,
               nres = 2,prune=15,
               type = "bisquare",
               subsamp = 20000)

### Now evaluate basis functions at origin
S <- eval_basis(G,matrix(c(0,0),1,2))
```

FRK

Construct SRE object, fit and predict

Description

The Spatial Random Effects (SRE) model is the central object in FRK. The function FRK provides a wrapper for the construction and estimation of the SRE object from data, using the functions SRE (the object constructor) and SRE.fit (for fitting it to the data). Please see [SRE-class](#) for more details on the SRE object's properties and methods.

Usage

```
FRK(f, data, basis = NULL, BAUs = NULL, est_error = TRUE,
    average_in_BAU = TRUE, fs_model = "ind", vgm_model = NULL,
    K_type = "block-exponential", n_EM = 100, tol = 0.01, method = "EM",
    lambda = 0, print_lik = FALSE, ...)
```

```
SRE(f, data, basis, BAUs, est_error = TRUE, average_in_BAU = TRUE,
    fs_model = "ind", vgm_model = NULL, K_type = "block-exponential")
```

```
SRE.fit(SRE_model, n_EM = 100L, tol = 0.01, method = "EM", lambda = 0,
    print_lik = FALSE)
```

```
SRE.predict(SRE_model, obs_fs = FALSE, pred_polys = NULL,
    pred_time = NULL)
```

Arguments

f	R formula relating the dependent variable (or transformations thereof) to covariates
data	list of objects of class SpatialPointsDataFrame, SpatialPolygonsDataFrame, STIDF, or STFDF. If using space-time objects, the data frame must have another field, t, containing the time index of the data point
basis	object of class Basis (or TensorP_Basis)
BAUs	object of class SpatialPolygonsDataFrame, SpatialPixelsDataFrame, STIDF, or STFDF. The object's data frame must contain covariate information as well as a field fs describing the fine-scale variation up to a constant of proportionality.

	If the function FRK is used directly, then BAUs are created automatically, but only coordinates can then be used as covariates
<code>est_error</code>	flag indicating whether the measurement-error variance should be estimated from variogram techniques. If this is set to 0, then data must contain a field <code>std</code> . Measurement-error estimation is currently not implemented for spatio-temporal datasets
<code>average_in_BAU</code>	if TRUE, then multiple data points falling in the same BAU are averaged; the measurement error of the averaged data point is taken as the average of the individual measurement errors
<code>fs_model</code>	if "ind" then the fine-scale variation is independent at the BAU level. If "ICAR", then an ICAR model for the fine-scale variation is placed on the BAUs
<code>vgm_model</code>	an object of class <code>variogramModel</code> from the package <code>gstat</code> constructed using the function <code>vgm</code> . This object contains the variogram model that will be fit to the data. The nugget is taken as the measurement error when <code>est_error = TRUE</code> . If unspecified, the variogram used is <code>gstat::vgm(1, "Lin", d, 1)</code> , where <code>d</code> is approximately one third of the maximum distance between any two data points
<code>K_type</code>	the parameterisation used for the K matrix. Currently this can be "unstructured" or "block-exponential" (default)
<code>n_EM</code>	maximum number of iterations for the EM algorithm
<code>tol</code>	convergence tolerance for the EM algorithm
<code>method</code>	parameter estimation method to employ. Currently only "EM" is supported
<code>lambda</code>	ridge-regression regularisation parameter for when K is unstructured (0 by default). Can be a single number, or a vector (one parameter for each resolution)
<code>print_lik</code>	flag indicating whether likelihood value should be printed or not after convergence of the EM estimation algorithm
<code>...</code>	other parameters passed on to <code>auto_basis</code> and <code>auto_BAUs</code> when calling the function FRK
<code>SRE_model</code>	object returned from the constructor <code>SRE()</code> containing all the parameters and information on the SRE model
<code>obs_fs</code>	flag indicating whether the fine-scale variation sits in the observation model (systematic error, Case 1) or in the process model (fine-scale process variation, Case 2, default)
<code>pred_polys</code>	object of class <code>SpatialPolygons</code> indicating the regions over which prediction will be carried out. The BAUs are used if this option is not specified
<code>pred_time</code>	vector of time indices at which prediction will be carried out. All time points are used if this option is not specified

Details

`SRE()` is the main function in the package: It constructs a spatial random effects model from the user-defined formula, data object, basis functions and a set of Basic Areal Units (BAUs). The function first takes each object in the list `data` and maps it to the BAUs – this entails binning the point-referenced data into the BAUs (and averaging within the BAU) if `average_in_BAU = TRUE`, and finding which BAUs are influenced by the polygon datasets. Following this, the incidence

matrix $Cmat$ is constructed, which appears in the observation model $Z = CY + C\delta + e$, where C is the incidence matrix and δ is systematic error at the BAU level.

The SRE model for the hidden process is given by $Y = T\alpha + S\eta + \xi$, where T are the covariates at the BAU level, α are the regression coefficients, S are the basis functions evaluated at the BAU level, η are the basis-function coefficients, and ξ is the fine scale variation (at the BAU level). The covariance matrix of ξ is diagonal, with its diagonal elements proportional to the field ‘fs’ in the BAUs (typically set to one). The constant of proportionality is estimated in the EM algorithm. All required matrices (S, T etc.) are initialised using sensible defaults and returned as part of the object, please see [SRE-class](#) for more details.

`SRE.fit()` takes an object of class `SRE` and estimates all unknown parameters, namely the covariance matrix K , the fine scale variance (σ_ξ^2 or σ_δ^2 , depending on whether Case 1 or Case 2 is chosen; see the vignette) and the regression parameters α . The only method currently implemented is the Expectation Maximisation (EM) algorithm, which the user configures through `n_EM` and `tol`. The log-likelihood (given in Section 2.2 of the vignette) is evaluated at each iteration at the current parameter estimate, and convergence is assumed to have been reached when this quantity stops changing by more than `tol`.

The actual computations for the E-step and M-step are relatively straightforward. The E-step contains an inverse of an $r \times r$ matrix, where r is the number of basis functions which should not exceed 2000. The M-step first updates the matrix K , which only depends on the sufficient statistics of the basis-function coefficients η . Then, the regression parameter α is updated and a simple optimisation routine (a line search) is used to update the fine-scale variance σ_δ^2 or σ_ξ^2 . If the fine-scale errors and measurement random errors are homoscedastic, then a closed-form solution is available for the update of σ_ξ^2 or σ_δ^2 . Irrespectively, since the updates of α , and σ_δ^2 or σ_ξ^2 , are dependent, these two updates are iterated until the change in σ^2 is no more than 0.1%.

The function `FRK` acts as a wrapper for the functions `SRE` and `SRE.fit`. An added advantage of using `FRK` directly is that it automatically generates BAUs and basis functions based on the data. Hence `FRK` can be called using only a list of data objects and an R formula, although the R formula can only contain space or time as covariates when BAUs are not explicitly supplied with the covariate data.

Once the parameters are fitted, the `SRE` object is passed onto the function `SRE.predict()` in order to carry out optimal predictions over the same BAUs used to construct the `SRE` model with `SRE()`. The first part of the prediction process is to construct the matrix S over the prediction polygons. This is made computationally efficient by treating the prediction over polygons as that of the prediction over a combination of BAUs. This will yield valid results only if the BAUs are relatively small. Once the matrix S is found, a standard Gaussian inversion (through conditioning) using the estimated parameters is used for prediction.

`SRE.predict` returns the BAUs, which are of class `SpatialPolygonsDataFrame`, `SpatialPixelsDataFrame`, or `STFDF`, with two added attributes, `mu` and `var`. These can then be easily plotted using `splot` or `ggplot2` (possibly in conjunction with [SpatialPolygonsDataFrame_to_df](#)) as shown in the package vignettes.

Examples

```
library(sp)

### Generate process and data
n <- 100
sim_process <- data.frame(x = seq(0.005, 0.995, length=n))
```

```

sim_process$y <- 0
sim_process$proc <- sin(sim_process$x*10) + 0.3*rnorm(n)

sim_data <- sim_process[sample(1:n,50),]
sim_data$z <- sim_data$proc + 0.1*rnorm(50)
sim_data$std <- 0.1
coordinates(sim_data) = ~x + y # change into an sp object
grid_BAUs <- auto_BAUs(manifold=real_line(),data=sim_data,
                      nonconvex_hull=FALSE,cellsize = c(0.01),type="grid")
grid_BAUs$fs = 1

### Set up SRE model
G <- auto_basis(manifold = real_line(),
               data=sim_data,
               nres = 2,
               regular = 6,
               type = "bisquare",
               subsamp = 20000)

f <- z ~ 1
S <- SRE(f,list(sim_data),G,
        grid_BAUs,
        est_error = FALSE)

### Fit with 5 EM iterations so as not to take too much time
S <- SRE.fit(S,n_EM = 5,tol = 0.01,print_lik=TRUE)

### Predict over BAUs
grid_BAUs <- SRE.predict(S)

### Plot
## Not run:
library(ggplot2)
X <- slot(grid_BAUs,"data")
X <- subset(X, x >= 0 & x <= 1)
g1 <- LinePlotTheme() +
  geom_line(data=X,aes(x,y=mu)) +
  geom_errorbar(data=X,aes(x=x,ymax = mu + 2*sqrt(var), ymin= mu - 2*sqrt(var))) +
  geom_point(data = data.frame(sim_data),aes(x=x,y=z),size=3) +
  geom_line(data=sim_process,aes(x=x,y=proc),col="red")
print(g1)
## End(Not run)

```

```

initialize,manifold-method
      manifold

```

Description

Manifold initialisation. This function should not be called directly as `manifold` is a virtual class.

Usage

```
## S4 method for signature 'manifold'
initialize(.Object)
```

Arguments

`.Object` manifold object passed up from lower-level constructor

 isea3h

ISEA Aperture 3 Hexagon (ISEA3H) Discrete Global Grid

Description

The data used here were obtained from <http://webpages.sou.edu/~sahrk/dgg/isea.old/gen/isea3h.html> and represent ISEA discrete global grids (DGGRIDs) generated using the DGGRID software. The original .gen files were converted to a data frame using the function `dggrid_gen_to_df`, available with the `dggrids` package. Only resolutions 0–6 are supplied with FRK and note that resolution 0 of ISEA3H is equal to resolution 1 in FRK. For higher resolutions `dggrids` can be installed from <https://github.com/andrewzm/dggrids> using devtools.

Usage

```
isea3h
```

Format

A data frame with 284,208 rows and 5 variables:

id grid identification number within the given resolution

lon longitude coordinate

lat latitude coordinate

res DGGRID resolution (0 – 6)

centroid A 0-1 variable, indicating whether the point describes the centroid of the polygon, or whether it is a boundary point of the polygon

References

Sahr, K. (2008). Location coding on icosahedral aperture 3 hexagon discrete global grids. *Computers, Environment and Urban Systems*, 32, 174–187.

local_basis	<i>Construct a set of local basis functions</i>
-------------	---

Description

Construct a set of local basis functions based on pre-specified location and scale parameters.

Usage

```
local_basis(manifold = sphere(), loc = matrix(c(1, 0), nrow = 1),
            scale = 1, type = c("bisquare", "Gaussian", "exp", "Matern32"))
```

```
radial_basis(manifold = sphere(), loc = matrix(c(1, 0), nrow = 1),
             scale = 1, type = c("bisquare", "Gaussian", "exp", "Matern32"))
```

Arguments

manifold	object of class manifold, for example, sphere
loc	a matrix of size n by dimensions(manifold) indicating centres of basis functions
scale	vector of length n containing the scale parameters of the basis functions; see details
type	either “bisquare”, “Gaussian”, “exp”, or “Matern32”

Details

This functions lays out local basis functions in a domain of interest based on pre-specified location and scale parameters. If type is “bisquare”, then

$$\phi(u) = \left(1 - \left(\frac{\|u\|}{R}\right)^2\right)^2 I(\|u\| < R),$$

and scale is given by R , the range of support of the bisquare function. If type is “Gaussian”, then

$$\phi(u) = \exp\left(-\frac{\|u\|^2}{2\sigma^2}\right),$$

and scale is given by σ , the standard deviation. If type is “exp”, then

$$\phi(u) = \exp\left(-\frac{\|u\|}{\tau}\right),$$

and scale is given by τ , the e-folding length. If type is “Matern32”, then

$$\phi(u) = \left(1 + \frac{\sqrt{3}\|u\|}{\kappa}\right) \exp\left(-\frac{\sqrt{3}\|u\|}{\kappa}\right),$$

and scale is given by κ , the function’s scale.

Examples

```
library(ggplot2)
G <- local_basis(manifold = real_line(),
                 loc=matrix(1:10,10,1),
                 scale=rep(2,10),
                 type="bisquare")
## Not run: show_basis(G)
```

manifold	<i>Retrieve manifold</i>
----------	--------------------------

Description

Retrieve manifold from FRK object.

Usage

```
manifold(.Object)

## S4 method for signature 'Basis'
manifold(.Object)

## S4 method for signature 'TensorP_Basis'
manifold(.Object)
```

Arguments

.Object FRK object

Examples

```
G <- local_basis(manifold = plane(),
                 loc=matrix(0,1,2),
                 scale=0.2,
                 type="bisquare")
manifold(G)
```

manifold-class	<i>manifold</i>
----------------	-----------------

Description

The class manifold is virtual; other manifold classes inherit from this class.

Details

A manifold object is characterised by a character variable `type`, which contains a description of the manifold, and a variable `measure` of type `measure`. A typical measure is the Euclidean distance.

FRK supports five manifolds; the real line (in one dimension), instantiated by using `real_line()`; the 2D plane, instantiated by using `plane()`; the 2D-sphere surface `S2`, instantiated by using `sphere()`; the `R2` space-time manifold, instantiated by using `STplane()`, and the `S2` space-time manifold, instantiated by using `STsphere()`. User-specific manifolds can also be specified, however helper functions that are manifold specific, such as `auto_BAUs` and `auto_basis`, only work with the pre-configured manifolds. Importantly, one can change the distance function used on the manifold to synthesise anisotropy or heterogeneity. See the vignette for one such example.

measure-class	<i>measure</i>
---------------	----------------

Description

Measure class used for defining measures used to compute distances between points in objects constructed with the FRK package.

Details

An object of class `measure` contains a distance function and a variable `dim` with the dimensions of the Riemannian manifold over which the distance is computed.

nbasis	<i>Number of basis functions</i>
--------	----------------------------------

Description

Retrieve the number of basis functions from `Basis` or `SRE` object.

Usage

```
nbasis(.Object)

## S4 method for signature 'Basis_obj'
nbasis(.Object)

## S4 method for signature 'SRE'
nbasis(.Object)
```

Arguments

`.Object` object of class `Basis` or `SRE`

Examples

```
library(sp)
data(meuse)
coordinates(meuse) = ~x+y # change into an sp object
G <- auto_basis(manifold = plane(),
                data=meuse,
                nres = 2,
                regular=1,
                type = "Gaussian")
print(nbasis(G))
```

NOAA_df_1990

NOAA maximum temperature data for 1990–1993

Description

Maximum temperature data obtained from the National Oceanic and Atmospheric Administration (NOAA) for a part of the USA between 1990 and 1993 (inclusive). See <http://iridl.ldeo.columbia.edu/SOURCES/.NOAA/.NCDC/.DAILY/.FSOD/>.

Usage

NOAA_df_1990

Format

A data frame with 196,253 rows and 8 variables:

year year of retrieval

month month of retrieval

day day of retrieval

z dependent variable

proc variable name (Tmax)

id station id

lon longitude coordinate of measurement station

lat latitude coordinate of measurement station

References

National Climatic Data Center, March 1993: Local Climatological Data. Environmental Information summary (C-2), NOAA-NCDC, Asheville, NC.

nres	<i>Return the number of resolutions</i>
------	---

Description

Return the number of resolutions from a basis function object.

Usage

```
nres(b)

## S4 method for signature 'Basis'
nres(b)

## S4 method for signature 'TensorP_Basis'
nres(b)

## S4 method for signature 'SRE'
nres(b)
```

Arguments

b object of class Basis or SRE

Examples

```
library(sp)
set.seed(1)
d <- data.frame(lon = runif(n=1000,min = -179, max = 179),
                lat = runif(n=1000,min = -90, max = 90),
                z = rnorm(5000))
coordinates(d) <- ~lon + lat
proj4string(d)=CRS("+proj=longlat")

### Now create basis functions on sphere
G <- auto_basis(manifold = sphere(),data=d,
               nres = 2,prune=15,
               type = "bisquare",
               subsamp = 20000)

nres(G)
```

 opts_FRK

FRK options

Description

The main options list for the FRK package.

Usage

opts_FRK

Format

List of 2

- `$ set: function(opt, value)`
- `$ get: function(opt)`

Details

opts_FRK is a list containing two functions, set and get, which can be used to set options and retrieve options, respectively. Currently FRK uses three options:

- "progress": a flag indicating whether progress bars should be displayed or not
- "verbose": a flag indicating whether certain progress messages should be shown or not
- "parallel": an integer indicating the number of cores to use. A number 0 or 1 indicates no parallelism

Examples

```
opts_FRK$set("progress", 1L)
opts_FRK$get("parallel")
```

 plane

plane

Description

Initialisation of a 2D plane.

Usage

```
plane(measure = Euclid_dist(dim = 2L))
```

Arguments

measure an object of class measure

Details

A 2D plane is initialised using a measure object. By default, the measure object (measure) is the Euclidean distance in 2 dimensions, [Euclid_dist](#).

Examples

```
P <- plane()
print(type(P))
print(sp::dimensions(P))
```

plotting-themes *Plotting themes*

Description

Formats a ggplot object for neat plotting.

Usage

```
LinePlotTheme()
EmptyTheme()
```

Details

LinePlotTheme() creates ggplot object with a white background, a relatively large font, and grid lines. EmptyTheme() on the other hand creates a ggplot object with no axes or legends.

Value

Object of class ggplot

Examples

```
## Not run:
X <- data.frame(x=runif(100),y = runif(100), z = runif(100))
LinePlotTheme() + geom_point(data=X,aes(x,y,colour=z))
EmptyTheme() + geom_point(data=X,aes(x,y,colour=z))
## End(Not run)
```

real_line	<i>real line</i>
-----------	------------------

Description

Initialisation of the real-line (1D) manifold.

Usage

```
real_line(measure = Euclid_dist(dim = 1L))
```

Arguments

measure an object of class measure

Details

A real line is initialised using a measure object. By default, the measure object (measure) describes the distance between two points as the absolute difference between the two coordinates.

Examples

```
R <- real_line()
print(type(R))
print(sp::dimensions(R))
```

remove_basis	<i>Removes basis functions</i>
--------------	--------------------------------

Description

Takes a an object of class Basis and returns an object of class Basis with selected basis functions removed.

Usage

```
remove_basis(Basis, rmidx)
```

```
## S4 method for signature 'Basis'
remove_basis(Basis, rmidx)
```

Arguments

Basis object of class Basis
 rmidx indices of basis functions to remove

Examples

```
library(sp)
df <- data.frame(x = rnorm(10),
                 y = rnorm(10))
coordinates(df) <- ~x+y
G <- auto_basis(plane(),df,nres=1)
data.frame(G) # Print info on basis
G <- remove_basis(G,1:(nbasis(G)-1))
data.frame(G)
```

show_basis	<i>Show basis functions</i>
------------	-----------------------------

Description

Generic plotting function for visualising the basis functions.

Usage

```
show_basis(basis, ...)

## S4 method for signature 'Basis'
show_basis(basis, g = ggplot() + theme_bw() + xlab("") +
           ylab(""))

## S4 method for signature 'TensorP_Basis'
show_basis(basis, g = ggplot())
```

Arguments

basis	object of class Basis
...	not in use
g	object of class gg (a ggplot object) over which to overlay the basis functions (optional)

Details

The function `show_basis` adapts its behaviour to the manifold being used. With `real_line`, the 1D basis functions are plotted with colour distinguishing between the different resolutions. With `plane`, only local basis functions are supported (at present). Each basis function is shown as a circle with diameter equal to the `scale` parameter of the function. Linetype distinguishes the resolution. With `sphere`, the centres of the basis functions are shown as circles, with larger sizes corresponding to coarser resolutions. Space-time basis functions of subclass `TensorP_Basis` are visualised by showing the spatial basis functions and the temporal basis functions in two separate plots.

Examples

```

library(ggplot2)
library(sp)
data(meuse)
coordinates(meuse) = ~x+y # change into an sp object
G <- auto_basis(manifold = plane(),data=meuse,nres = 2,regular=2,prune=0.1,type = "bisquare")
## Not run: show_basis(G,ggplot()) + geom_point(data=data.frame(meuse),aes(x,y))

```

SpatialPolygonsDataFrame_to_df
SpatialPolygonsDataFrame to df

Description

Convert SpatialPolygonsDataFrame object to data frame.

Usage

```
SpatialPolygonsDataFrame_to_df(sp_polys, vars = names(sp_polys))
```

Arguments

sp_polys	object of class SpatialPolygonsDataFrame
vars	variables to put into data frame (by default all of them)

Details

This function is mainly used for plotting SpatialPolygonsDataFrame objects with ggplot rather than spplot. The coordinates of each polygon are extracted and concatenated into one long data frame. The attributes of each polygon are then attached to this data frame as variables that vary by polygon id (the rownames of the object).

Examples

```

library(sp)
library(ggplot2)
opts_FRK$set("parallel",0L)
df <- data.frame(id = c(rep(1,4),rep(2,4)),
                 x = c(0,1,0,0,2,3,2,2),
                 y=c(0,0,1,0,0,1,1,0))
pols <- df_to_SpatialPolygons(df,"id",c("x","y"),CRS())
polsdf <- SpatialPolygonsDataFrame(pols,data.frame(p = c(1,2),row.names=row.names(pols)))
df2 <- SpatialPolygonsDataFrame_to_df(polsdf)
## Not run: ggplot(df2,aes(x=x,y=y,group=id)) + geom_polygon()

```

sphere	<i>sphere</i>
--------	---------------

Description

Initialisation of the 2-sphere, S2.

Usage

```
sphere(radius = 6371)
```

Arguments

radius	radius of sphere
--------	------------------

Details

The 2D surface of a sphere is initialised using a radius parameter. The default value of the radius R is R=6371 km, Earth's radius, while the measure used to compute distances on the sphere is the great-circle distance on a sphere of radius R.

Examples

```
S <- sphere()
print(sp::dimensions(S))
```

SRE-class	<i>Spatial Random Effects class</i>
-----------	-------------------------------------

Description

This is the central class definition of the FRK package, containing the model and all other information required for estimation and prediction.

Details

The spatial random effects (SRE) model is the model employed in Fixed Rank Kriging, and the SRE object contains all information required for estimation and prediction from spatial data. Object slots contain both other objects (for example, an object of class `Basis`) and matrices derived from these objects (for example, the matrix S) in order to facilitate computations.

Slots

- f formula used to define the SRE object. All covariates employed need to be specified in the object BAUs
- data the original data from which the model's parameters are estimated
- basis object of class Basis used to construct the matrix S
- BAUs object of class SpatialPolygonsDataFrame, SpatialPixelsDataFrame of STDF that contains the Basic Areal Units (BAUs) that are used to both (i) project the data onto a common discretisation if they are point-referenced and (ii) provide a BAU-to-data relationship if the data has a spatial footprint
- S matrix constructed by evaluating the basis functions at all the data locations (of class Matrix)
- S0 matrix constructed by evaluating the basis functions at all BAUs (of class Matrix)
- D_basis list of distance-matrices of class Matrix, one for each basis-function resolution
- Ve measurement-error variance-covariance matrix (typically diagonal and of class Matrix)
- Vfs fine-scale variance-covariance matrix at the data locations (typically diagonal and of class Matrix) up to a constant of proportionality estimated using the EM algorithm
- Vfs_BAUs fine-scale variance-covariance matrix at the BAU centroids (typically diagonal and of class Matrix) up to a constant of proportionality estimated using the EM algorithm
- Qfs_BAUs fine-scale precision matrix at the BAU centroids (typically diagonal and of class Matrix) up to a constant of proportionality estimated using the EM algorithm
- Z vector of observations (of class Matrix)
- Cmat incidence matrix mapping the observations to the BAUs
- X matrix of covariates
- K_type type of prior covariance matrix of random effects. Can be "block-exponential" (correlation between effects decays as a function of distance between the basis-function centroids), or "unstructured" (all elements in K are unknown and need to be estimated)
- mu_eta updated expectation of random effects (estimated)
- S_eta updated covariance matrix of random effects (estimated)
- Q_eta updated precision matrix of random effects (estimated)
- Khat prior covariance matrix of random effects (estimated)
- Khat_inv prior precision matrix of random effects (estimated)
- alphahat fixed-effect regression coefficients (estimated)
- sigma2fshat fine-scale variation scaling (estimated)
- fs_model type of fine-scale variation (independent or CAR-based). Currently only "ind" is permitted

STplane	<i>plane in space-time</i>
---------	----------------------------

Description

Initialisation of a 2D plane with a temporal dimension.

Usage

```
STplane(measure = Euclid_dist(dim = 3L))
```

Arguments

measure an object of class measure

Details

A 2D plane with a time component added is initialised using a measure object. By default, the measure object (measure) is the Euclidean distance in 3 dimensions, [Euclid_dist](#).

Examples

```
P <- STplane()
print(type(P))
print(sp::dimensions(P))
```

STsphere	<i>Space-time sphere</i>
----------	--------------------------

Description

Initialisation of a 2-sphere (S²) with a temporal dimension

Usage

```
STsphere(radius = 6371)
```

Arguments

radius radius of sphere

Details

As with the spatial-only sphere, the sphere surface is initialised using a radius parameter. The default value of the radius R is $R=6371$, which is the Earth's radius in km, while the measure used to compute distances on the sphere is the great-circle distance on a sphere of radius R . By default Euclidean geometry is used to factor in the time component, so that $\text{dist}((s1,t1),(s2,t2)) = \sqrt{\text{gc_dist}(s1,s2)^2 + (t1 - t2)^2}$. Frequently this distance can be used since separate correlation length scales for space and time are estimated in the EM algorithm (that effectively scale space and time separately).

Examples

```
S <- STsphere()
print(sp::dimensions(S))
```

TensorP	<i>Tensor product of basis functions</i>
---------	--

Description

Constructs a new set of basis functions by finding the tensor product of two sets of basis functions.

Usage

```
TensorP(Basis1, Basis2)

## S4 method for signature 'Basis,Basis'
TensorP(Basis1, Basis2)
```

Arguments

Basis1	first set of basis functions
Basis2	second set of basis functions

Examples

```
library(spacetime)
library(sp)
library(dplyr)
sim_data <- data.frame(lon = runif(20,-180,180),
                      lat = runif(20,-90,90),
                      t = 1:20,
                      z = rnorm(20),
                      std = 0.1)
time <- as.POSIXct("2003-05-01",tz="") + 3600*24*(sim_data$t-1)
space <- sim_data[,c("lon","lat")]
coordinates(space) = ~lon+lat # change into an sp object
proj4string(space)=CRS("+proj=longlat +ellps=sphere")
STobj <- STIDF(space,time,data=sim_data)
```

```
G_spatial <- auto_basis(manifold = sphere(),
                        data=as(STobj,"Spatial"),
                        nres = 1,
                        type = "bisquare",
                        subsamp = 20000)
G_temporal <- local_basis(manifold=real_line(),loc = matrix(c(1,3)),scale = rep(1,2))
G <- TensorP(G_spatial,G_temporal)
# show_basis(G_spatial)
# show_basis(G_temporal)
```

type	<i>Type of manifold</i>
------	-------------------------

Description

Retrieve slot type from object

Usage

```
type(.Object)

## S4 method for signature 'manifold'
type(.Object)
```

Arguments

.Object object of class Basis or manifold

Examples

```
S <- sphere()
print(type(S))
```

worldmap	<i>World map</i>
----------	------------------

Description

This world map was extracted from the package maps v.3.0.1 by running `map_data("world")`. To reduce the data size, only every third point of this data frame is contained in `worldmap`.

Usage

```
worldmap
```

Format

A data frame with 33971 rows and 6 variables:

long longitude coordinate

lat latitude coordinate

group polygon (region) number

order order of point in polygon boundary

region region name

subregion subregion name

References

Original S code by Becker, R.A. and Wilks, R.A. This R version is by Brownrigg, R. Enhancements have been made by Minka, T.P. and Deckmyn, A. (2015) maps: Draw Geographical Maps, R package version 3.0.1.
